# GOOD SAMARITANS AND THE MARKET: EXPERIMENTAL EVIDENCE ON OTHER- REGARDING PREFERENCES IN PARTNERSHIP FORMATION

## Abstract

We construct an experiment to study the role of other-regarding preferences in the process of partnership formation. The literature on decentralized matching describes the process of match formation as a market-like process while the literature on other-regarding preferences suggests that such preferences are particularly strong in small partnerships. So we ask: do people apply market-like heuristics when searching for a partner (i.e. behave selfishly); or do they behave more pro-socially, as they do once these partnerships or small entities are formed? And if they do behave differently, what motivates differences in behavior? We focus on one possible mechanism explaining differences in behavior: the saliency of the implications of choices on others. We compare partnership choices in three treatments, varying the saliency of the implications of choices on others. We find that a market-like situation reduces the 'good samaritan' spirit in this environment as well: when choosing a partner agents are less likely to sacrifice their own material well-being to increase the well-being of others.

December 2015

## Abstract

We construct an experiment to study the role of other-regarding preferences in the process of partnership formation. The literature on decentralized matching describes the process of match formation as a market-like process while the literature on other-regarding preferences suggests that such preferences are particularly strong in small partnerships. So we ask: do people apply market-like heuristics when searching for a partner (i.e. behave selfishly); or do they behave more pro-socially, as they do once these partnerships or small entities are formed? And if they do behave differently, what motivates differences in behavior? We focus on one possible mechanism explaining differences in behavior: the saliency of the implications of choices on others. We compare partnership choices in three treatments, varying the saliency of the implications of choices on others. We find that a market-like situation reduces the ‘good samaritan’ spirit in this environment as well: when choosing a partner agents are less likely to sacrifice their own material well-being to increase the well-being of others.

## 1 Motivation

Partnership formation is at the core of economic and social life: friendships, marriages, business partnerships or political alliances are a fundamental underpinning of economic and social exchange. In turn, this network of partnerships and social ties sustains societal divides along many socio-economic dimensions such as race, religion or education (McPherson, 2001).

Very often partnerships are formed voluntarily, and arise from a process that entails choosing one another and agreeing on how the gains from partnership are shared. There is many examples

---

\*Department of Economics, University of Edinburgh

†Department of Economics, Oxford University

of pairings of two types of agents – e.g., producers and investors, farmers and landowners, advisors and advisees – in which collaboration is voluntary and entail a sharing agreement. The sorting patterns resulting from such partnership formation play a crucial role in the allocation of resources within a society, both in terms of efficiency and equality. Economists and sociologists have long been interested in how relationships are formed and who matches with whom, starting with the early work by Becker (1973).

This paper studies the role of other-regarding preferences in the process of partnership formation. The literature on decentralized matching is agnostic as to what role these preferences may play. But there is now a well established literature on social preferences (Fehr and Schmidt 1999, Bolton and Ockenfels 2006, Charness and Rabin 2002, Cooper and Kagel 2013) showing that people are willing to transfer resources to others, in particular if these transfers reduce inequality, and that the role of other-regarding preferences seems particularly salient in the context of small partnerships. Take the example of household production. Without a modicum of altruism, free-riding would limit the provision of household public goods, making households less efficient and, hence, less likely to survive as production and consumption units. Given how important household stability must have been for reproductive success over the course of human history, we expect human societies to have developed strong norms and behavioral traits that favor other-regarding behavior within small groups (e.g., Fehr and Schmidt 1999, Ledyard, 1995, Camerer, 2003, Henrich et al. 2005).

In contrast, exchange in competitive markets can deliver an efficient outcome even if all participants act to maximize their own material welfare and nothing else. The original insight goes back to Adam Smith’s shoemaker parable, and it has been verified in numerous market experiments (e.g., Smith 1962). Indeed, in a review of the experimental evidence, Bowles (1998) observes that the more the experimental situation approximates a competitive (and complete contracts) market with many anonymous buyers and sellers, the less other-regarding behavior is observed. This finding fits with the two apparently opposite views of Adam Smith who argues in the *Wealth of Nations* (1776) that self-interest prevails in markets, while acknowledging the pro-sociality of human nature

in the *Theory of Moral Sentiments* (1759). Vernon Smith (1998) points out that these two forms of human nature are not contradictory but apply to different contexts. Selfish behavior maximizes the gains from impersonal market exchange, while cooperative behavior maximizes the gains from non-market personal exchange.

So far, little is known as to what role do other-regarding preferences play in partnership formation. The literature on decentralized matching describes the process of match formation as a market-like process while the literature on other-regarding preferences suggests that such preferences are particularly strong in small partnerships. So the question is: do people apply market-like heuristics when searching for a partner (i.e. behave selfishly); or do they behave more pro-socially, as they do once these partnerships or small entities are formed? And if they do behave differently, what motivates differences in behavior?

There could be many reasons why markets trigger different heuristics than small group allocation decisions. We are interested in exploring one particular mechanism here, which is that in a market context it may be cognitively more difficult to understand the implications of one's decision on others. To illustrate, imagine one remaining bread and several consumers. In a small group allocation, it is immediately obvious that taking the last bread has implications on others. People may therefore feel morally or socially obliged to share or let others have the remaining bread. In contrast, if the bread is the last one at the shop, the implications of taking it on others are less obvious and less salient. We suspect that many people will take the last bread if they can, and will feel little guilt for depriving others from it. Similarly in a partnership context, we conjecture that asking people to choose a partner among many candidates may trigger selfish heuristics because the implications for the rest of society are not obvious to them.

The goal of this study is to understand to what extent this mechanism is at work. Abstracting from strategic considerations, we want to see if putting people in a large group setting and asking them to choose a partner triggers different heuristics than when they are in a small group setting and are asked to take an allocation decision. Going from one setting to the other varies two features: One is the framing of the decision: partnership formation versus allocation decision; second is the

size of the group people are in. Both features may make it harder to realise the implications of one's decision for the others.

We conduct an experiment in the laboratory. We consider an environment with two "categories" of people intended to represent, in an uncontextualized way, the two sides of a partner selection choice. The two categories we consider are labeled "Addition" and "Multiplication" and correspond to an effort task performed at the beginning of the experiment. We invite 24 people in each experimental session. Participants are assigned at random to one of these two categories and, based on their performance in the real effort task, to one of two types – 'high' and 'low'. That is, in each session, we have 6 participants of each type and each category.

The first treatment we introduce is a *dictator allocation decision* involving themselves and three other subjects. Each group of four subjects includes two high and two low types from each category. Participants are asked to choose between two divisions of payoffs among the four of them, with no reference to partner selection. In a second treatment, we present the same allocation problem, but the decision is framed as a *choice between a high or low partner*. In the third treatment the allocation problem is also framed as a choice of partner, but unlike in treatment 2 the decision is among the twelve players of the other category. The latter treatment is the partnership formation context we are interested in. Going from Treatment 3 to Treatment 2 changes the size of the group (large group vs small group) but keeps the decision as a partner selection decision; while going from Treatment 2 to Treatment 1 changes the frame of the decision (partner selection vs allocation decision). In the first treatment, the implications that decisions have on others are obvious and salient. They become less salient as we move towards Treatment 3.

In the two latter treatments, experimental subjects are shown the payoff distributions associated with all four types of partnerships. In all three cases, the decision of one of four players is selected at random and implemented in a unilateral manner to determine the payoff of all four. This allows us to abstract from strategic considerations when we infer preferences from choices.

We consider different types of other-regarding preferences: pro-social preferences (Fehr and Schmidt 1995; Bolton and Ockenfels 2006); invidious preferences (Blanchflower and Oswald 2004;

Fafchamps and Shilpi 2008); and preferences for efficiency (Charness and Rabin 2002). In our design we separately vary the implication and saliency of partner choice on efficiency and income distribution. We study unilateral partnership formation - i.e., partnership formation without mutual consent – in order to identify preferences separately from strategic considerations in partnership formation.

In our three experimental treatments we find that participants mostly follow their material self-interest. This is in line with numerous studies of behavior in market games. We find a significant difference in partner selection between large groups (treatment 3) and small groups (treatment 2), but a much smaller difference between treatment 2 and the group treatment 1. This suggests that participants display other regarding preferences whenever they perceive their decision has a direct impact on others. In treatment 3 they are less likely to sacrifice their individual payoff to increase aggregate efficiency. As a result aggregate efficiency falls since the design rules out the operation of competitive forces. There is little or no statistical difference between treatments 1 and 2.

Because we experimentally assign participants to different average payoffs, we can test whether deviation from pure selfish behavior varies with expected income from the experiment. We find that high payoff agents are on average more altruistic than low payoff agents, but significantly less so in a partner selection environment. Similarly, low payoff agents are less reluctant to reduce others' payoff in a partner selection environment, particularly if the number of participants is large. We interpret these findings as suggesting that a large partner-selection environment reduces the 'good samaritan' spirit: agents are less likely to sacrifice their own material well-being to increase the well-being of others.

The paper is structured as follows. Section 2 presents the experimental design and the different treatments. The testing strategy is outlined in Section 3. Empirical results are presented in Sections 4 and 5.

## 2 Experimental Design

Participants play in sessions of 24<sup>1</sup> and participants in a session only play one treatment – i.e., we use a ‘between subjects’ design. A detailed description of the experimental protocol is given in Appendix.

### 2.1 Stages

Within each session the experiment is divided into two stages. In the first stage, the pool of participants is divided equally and randomly into two categories  $A$  and  $M$ .<sup>2</sup> The two categories are intended to represent, in an uncontextualized way, the two sides of a matching game, e.g., bride-groom, employer-employee, or hospital-intern. Having been assigned to a category, each participant individually completes a computerized task. Subjects are asked to do simple calculations for a period of 3 minutes – additions or multiplications depending on the category,  $A$  or  $M$ , to which they have been randomly allocated. Based on their performance in the task relative to other participants in the same session and category, they are assigned one of two types – bottom 50% or top 50%. Here we denote the two types simply as ‘high’ and ‘low’.

In the second stage of the experiment, participants play six rounds of an allocation game. No feedback is provided to participants until the end of the experiment, at which time they are only told their final payoff. Since payoffs are based on one randomly selected round, it is impossible for participants to infer the choices of other participants. The purpose of this is to rule out repeated games and strategic play: each round is de facto a dictator game with anonymous others and no feedback.

In the first two treatments, participants are assigned to groups of four. Each group consists of a low and high type participant from each category. In treatment 1 (T1) choices are presented as a selection between two ‘pies’ divided into four possibly unequal slices – see Instructions in Appendix A. For each round, each participant in each group selects his favorite pie/allocation. At the end

---

<sup>1</sup>In 3 sessions (one for each treatment), the number of people who reported for the experiment was less than 24. Hence the experiment was played in groups of 20 instead. This does not affect the experiment except in treatment 3.

<sup>2</sup>In the experiment these categories are referred to as ‘Addition’ and ‘Multiplication’ – see below.

of the session, one subject from each group and one round are selected at random, and his/her choice determines the payoff of all four participants in the group. The structure of the game thus resembles a dictator game with four players.

In treatment 2 (T2) participants are asked to indicate whether they would prefer to form a partnership with the low or high type participant from the other category. They are shown how the payoffs would be distributed for each possible partnership (high  $A$ /high  $M$ , high  $A$ /low  $M$ , low  $A$ /low  $M$ , low  $A$ /high  $M$ ). They are also made aware of the implications of their choice for the 2 other participants in their group (see Instructions for Treatment 2 in Appendix 3). For example, if a participant in category  $M$ , say, selects the high type in category  $A$  as partner, this also determines the payoff of the two remaining players since they can now only be matched with each other. As in treatment 1, final payoffs are determined by randomly selecting one round and one subject from each group, and letting his/her choice of partner determine the payoff of all four participants in the group.

In treatment 3 (T3), all 24 participants in a session play a partner selection game together as follows. Each participant is asked to select one of two possible types of partners, high or low, among players of the other category. Since the 24 participants are divided equally between categories  $A$  and  $M$ , and subsequently divided equally between low and high type within each category, there are six participants in each category  $\times$  type. Because players are anonymous and there is no feedback, the choice of each player resembles treatment 2 except for the larger number of players. They are also shown how the payoffs would be distributed for each possible partnership, as in treatment 2. But they are not told anything explicitly about the implications of their choice for others. To understand these implications, they need to understand that by choosing a partner of a certain type, they prevent one person from their own category to be matched to a partner of that particular type.

Payoffs in treatment 3 are determined as follows. We first randomly select one category ( $A$  or  $M$ ) at random as well as one of six rounds. We then aggregate the choices of the participants in the selected category. If there is excess demand for one type, then the scarce type is allocated in a

random manner between those who have expressed a preference for it. For instance, say category  $A$  is selected. Of the 12 participants in category  $A$ , 8 have selected to match with a high type. Since there are only 6 high types in category  $M$ , each of the 8 participants is allocated to a high type match with a probability equal to  $6/8$ , and a low type match with probability  $2/8$ . The 4 participants who have selected to match with a low type get their choice of type. The payoff determination process is explained in detail to participants before the experiment (see Instructions in Appendix for details).

In treatment 1, it is obvious by design that selecting one pie affects one's payoff and that of three other players. In treatment 2, it is clear to each player that their choice affects the payoff of the partner they choose. Given the payoff determination rule, they can also deduce that selecting one partner de facto forces the other two players together. Alternatively they may follow a market logic and convince themselves that their choice directly affects only one other player, and hence that their other-regarding preferences only apply to that player.

In treatment 3 players can, as in treatment 2, clearly see the effect of their choice on their – yet to be determined – *partner*. But by taking one possible partner away from the choice set of other participants, they also de facto limit the choices of other players. This effect is less salient than in treatment 2, however.<sup>3</sup> Because of the various rounds of randomization that take place before payoffs are assigned, treatment 3 may blur the sense of responsibility that participants associate with their actions. We call this the ‘dilution hypothesis’. A formal presentation of this hypothesis is given Appendix B.

## 2.2 Payoffs

Payoffs in the second stage of treatments 2 and 3 represent how gains from matching are shared between matched partners. Gains are always shared equally if both partners are of the same type (both high or both low). If partners are of different types, the division of payoffs differs from game to game so as to vary the efficiency and equity of an heterogeneous match. We call each payoff

---

<sup>3</sup>See Online Appendix A for a detailed discussion.

matrix a scenario.

In a session all participants play 6 different scenarios. The scenarios are the same for all the participants in the same session. The same set of scenarios/payoff matrices is used for the three treatments. We use a set of 17 different scenarios (see Table 2). In 12 scenarios, payoffs are such that an heterogeneous match – and hence negative assorting (e.g., low  $A$  with high  $M$ ) – is more efficient; in 6 scenarios, payoffs are such that positive sorting is efficient. We also have one scenario where positive and negative sorting are both efficient.

We also vary how the gains from a match are divided between the two participants. The three different division rules used are summarized in Table 1.

<b>Table 1. Possible sharing rules</b>		
	Low $A$	High $A$
Low $M$	1/2,1/2	1/2,1/2 1/3, 2/3 1/6, 5/6
High $M$	1/2,1/2 2/3, 1/3 5/6, 1/6	1/2,1/2

The scenarios are summarized in Table 2 where are reported the payoffs associated with the different types of partnerships (or different allocations in treatment 1). The different scenarios have been chosen so that we can assign as unambiguously as possible a sequence of choices made by an individual subject to a specific preference archetype, provided that the subject’s choices are all consistent with that archetype. We come back to this in Section 3.4.

High types have higher payoffs on average, and low types low payoffs. To help identify other-regarding preferences,<sup>4</sup> we introduce a further payoff differentiation between low  $A$  and low  $M$  payoffs such that low  $M$  types get, on average, lower payoffs than low  $A$  types. Throughout the analysis we present results broken down by these three payoff categories.

It is important to realize that in each T2 and T3 scenario participants ultimately choose between two possible pairings: (1) high  $A$ -high  $M$  / low  $A$ -low  $M$  and (2) high  $A$ -low  $M$  / low  $A$  - high  $M$ .

---

<sup>4</sup>Specifically, we need this design to distinguish between selfish preferences and maximin preferences for low types.

The first corresponds to positive assorting, the second to negative assorting. Each of the pairings has an associated total payoff for the four participants affected by someone’s choice. Hence to each scenario is associated two possible efficiency values. In some scenarios positive assorting is efficient; in others negative assorting is efficient. Treatment T1 mimics these differences albeit without explicit assorting. In all but 3.8% of the observations one form of assorting is more efficient than the other. However, whether positive or negative assorting maximizes someone’s material payoff varies by category and type and according to the sharing rule associated with a particular scenario (see Table 1).

Treatments may affect expressed preferences in different ways. Because treatment 1 resembles the allocation process that takes place within a household, where some members (e.g., the person in charge of grocery shopping) make choices for other members, it may elicit preferences that are more other-regarding. One possibility is that participants pay more attention to the efficiency cost of their action. Another is that they seek a more equal allocation of payoff, or that they are less spiteful.

Because treatment 3 resembles an anonymous market environment, participants may use market heuristics when making choices, feeling empowered to pursue their own material welfare and thereby ignoring the consequences of their choice on others. Treatments 2 and 3 also raise the possibility that players may prefer to match with someone of their type (e.g., high or low) – see for instance Curriani and Mengel (2011) for recent evidence of homophily in experiments with randomly assigned types.

### **3 Analysis and results**

The experiment took place at the experimental laboratory of the Centre for Experimental Social Sciences in May and November 2011.<sup>5</sup> We ran 12 sessions (4 sessions per treatment). 308 participants took part in total. Participants earned £10.28 on average.

---

<sup>5</sup>We ran the sessions corresponding to Treatment 3 in June 2011 and those corresponding to Treatments 1 and 2 in November 2011.

The first objective of the experiment is to test whether play is systematically different between treatments and, in particular, whether decisions are more sensitive to (1) the payoffs of others and (2) to efficiency considerations as the saliency of the implications of choices increases. The second objective is to test what type of preference is most likely to account for observed behavior. We report on these two objectives in turn.

### 3.1 Sensitivity to the payoffs of others

Throughout we denote by  $\pi_i$  the payoff of subject  $i$  and  $N_i$  be the set of four players affected by  $i$ 's choice.<sup>6</sup> We define efficiency as the sum of the payoffs of the four participants affected by the choice of a single player.

#### 3.1.1 Variation across treatments

We begin by showing that play varies systematically with treatments. The right panel of Table 2 presents the raw aggregate distribution of choices for each scenario. We present the share of participants choosing a partner of the same type. We observe large differences across types and across scenarios.

In the upper left panel of Table 3 we report, for each treatment, the proportion of times a subject picks the choice that maximizes his or her individual payoff. The first three columns present the average for each of the three treatments, while the last columns reports the test statistic and  $p$ -value for a  $\chi^2$  square test of equality of means across treatments. Results are presented separately for subjects assigned to high payoff, low payoff in the  $A$  category, and low payoff in the  $M$  category. As indicated earlier, low payoffs for subjects experimentally assigned to the  $A$  category are higher than for those assigned to the  $M$  category. We see that most choices are those that maximize the subject's material payoff. There is little difference across treatments, and whatever differences are present are not statistically significant. We also note that the proportion of choices consistent with selfish preferences is highest for low average payoff participants and lowest for high average payoff

---

<sup>6</sup>In treatment 3, the exact individuals affected are unknown prior to ex post randomization, but their payoffs are known since, by design, they belong to the four category  $\times$  type groups. See appendix for a formal demonstration.

participants.

The upper right panel of Table 3 shows the proportion of times that a subject picks the choice that maximizes the payoff of the other three players affected by their choice. As before, we report proportions under each of the three treatments as well as the results of a  $\chi^2$  square test of equality of means across treatments. Results are presented separately for high payoff subjects, and low payoff subjects assigned to the *A* or *M* category.

The proportion of choices that maximizes others' payoffs decreases systematically as we go from treatment T1 to treatment T3. This is true for all payoff categories, but is strongest and highly significant for high payoff participants. For the lowest payoff types, those in category *M*, the difference is not statistically significant at standard levels. For the low payoff participants in the *A* category, the difference is significant at the 10% level. This suggests that participants take others' payoff less into consideration as we move from treatment T1 to treatments T2 and T3, but more so if their average payoff is higher. We also note that the magnitude of the increase in proportions is similar between treatments T1 and T2 and between T2 and T3.

In many cases, the choice that maximizes the payoff of others also maximizes one's own payoff. This explains why it is possible for, say, high payoff subjects in treatment T3 to maximize their own payoff in 80.8% of the cases while at the same time maximizing the other players' payoff in 52.7% of the cases. To investigate this issue further, in the lower half of Table 3 we split the choices that maximize others' payoff depending on whether doing so also maximizes one's own payoff or not. The 'good Samaritan' spirit correspond to the case where participants maximize others' payoff even though doing so reduces their own. This case is displayed in the lower right panel of Table 3. In the lower left panel panel we show the proportion of choices that maximize others' payoff when doing so also maximizes the subject's own material payoff. Such choices are consistent with efficiency consideration but are less remarkable from an equity point of view.

In the lower left-hand panel we find that participants are more sensitive to aggregate efficiency in treatment T1 than in partner-selection treatments T2 and T3. This is true for all three payoff categories of participants, but only significantly so for high payoff participants. From the lower

right-hand panel, we see that the good Samaritan spirit is highest in treatment T1 and lowest in T3. The difference is large in magnitude and significant at the 1% level for high and category *A* low payoff participants; for category *M* low payoff participants the difference is smaller in magnitude and only significant at the 16% level. These low payoff participants thus seem to focus exclusively on their own payoff, and show little regard for the payoff of others. One possible explanation is that they are trying to make up for having been assigned to the lowest payoff category at the onset of the experiment.

To further verify our results, we investigate whether treatments affect the sensitivity of participants' choice to differences in payoffs between the two options they face. Let  $\Delta\pi_i \equiv \pi_i^h - \pi_i^l$  be the gain in *i*'s payoff from choosing a high partner (or equivalent allocation in T1). Similarly let  $\Delta\pi_{-i} \equiv \sum_{j \neq i, j \in N_i} (\pi_j^h - \pi_j^l)$  be the gain in the payoff of the other three players affected by *i*'s choice. To calculate the marginal effects of  $\Delta\pi_i$  and  $\Delta\pi_{-i}$  on the probability of choosing a high partner (or equivalent allocation in T1) we estimate a regression model of the form:

$$y_i = \Delta\pi_i \otimes T \otimes X + \Delta\pi_{-i} \otimes T \otimes X + \varepsilon_i \quad (1)$$

where  $\Delta\pi_i \otimes T \otimes X$  is shorthand for all the possible interaction terms between them and similarly for  $\Delta\pi_{-i} \otimes T \otimes X$ .<sup>7</sup> Regression (1) is estimated using a linear probability model with standard errors clustered at the session level.

We report in Table 4 the estimated marginal effects with their *t*-value for each of the  $T \otimes X$  combinations. What the Table reveals is that choice sensitivity to the payoff difference between the two options is comparable across treatments: a one unit increase in payoff gain increases the probability of choosing the more beneficial option by 5 to 6 percentage points across all subject types and treatments. Since the standard deviation of  $\Delta\pi_i$  is 4.67, this is a large effect. There is a decrease in sensitivity to own payoff in treatment T1 for high types and low *A* types, but the difference is relatively small in magnitude, not statistically significant, and we observe nothing similar for low *M* types.

---

<sup>7</sup>In other words, we include terms in  $\pi_i, T, X, TX, \pi_i T, \pi_i X$  and  $\pi_i TX$  where *T* and *X* are themselves vectors of dummies. Similarly for  $\pi_{-i}, T$  and *X*.

In contrast, choice sensitivity to  $\Delta\pi_{-i}$  varies dramatically across treatments and subject types. For high types – who on average earn higher payoffs – sensitivity to  $\Delta\pi_{-i}$  is absent in treatment T3 but present in the other two treatments. The effect is large in magnitude: a one standard deviation (i.e., 7.67) increase in  $\Delta\pi_{-i}$  raises the probability of choosing high by 7.5% in treatment T2 and 11.8% in treatment T1. In treatment T3 the effect is numerically 0. This suggests that among these players considerations of altruism or efficiency are eliminated in T3, a finding that is consistent with the dilution hypothesis.

Results are different for low types. Here we find that, under anonymous partner selection T3, low type participants are at the margin *less* likely to choose a high partner if other players benefit more from that choice, controlling for their own payoff gain. The effect is large in magnitude, especially for low  $A$  types: a one standard deviation increase in  $\Delta\pi_{-i}$  reduces the probability of choosing high by 11.4% for low  $A$  and 7.1% for low  $M$  types.

These findings are to be read in the context of the literature on inequality aversion (e.g., Fehr and Schmidt 1999, Okada and Reidl 2005). Experimental evidence has suggested that individuals display a desire to reduce the difference between their payoff and that of others both from above and from below. In other words, if a subject has a high payoff relative to other participants, this subject is often observed taking redistributive actions that reduce the difference between her payoff and that of other participants. This is consistent with the behavior of high types in our experiment, who have higher average payoffs and, in treatments T2 and T1, are more likely to choose an action that increases the payoff of other participants who, on average, earn a lower payoff. In other words, high types often choose an action that reduces the difference between their payoff and the lower payoff of others.

Also according to inequality aversion, a subject who has a low payoff relative to others often takes actions that increase her payoff at the expense of others. This is what we observe low types do in treatment 3: controlling for their own payoff, low types – who on average earn lower payoffs – are more likely to take an action that reduces the payoff of others. What is interesting is that, in our experiment, the two behaviors do not coexist: altruism (inequality aversion from above) is

only present in treatments that emphasize the effect one's choice has on several others; envy or spite (inequality aversion from below) is only present in the treatment that blurs the effect of one's choice on others. This suggests that the dilution effect reduces altruism/efficiency considerations, but not envy which is, rather, exacerbated by anonymity. In other words, the two sides of inequality aversion respond differentially to an anonymous market/partner selection environment: altruism is blunted by it, while envy is increased. In our experiment, the two effects together combine to reduce the efficiency of participants' choices.

### **3.1.2 Choices and efficiency**

We next investigate the relationship between treatment and the efficiency of individual choices. We ignore the 60 observations in which choices generate the same total payoff for the four players affected by ego's choice. We focus on whether the choice ego makes is efficient or not. In treatment T1 participants choose the efficient allocation in 70% of the observations. This proportion falls to 67% in T2 and 61% in T3. This difference is statistically significant at the 1% level.

We reproduce this finding in the first column of Table 5. Treatment T3 is the default category so that reported coefficients capture the efficiency gain of individual choices in T2 and T1 relative to T3. Furthermore, if we test average efficiency between T1 and T2, the difference is not statistically significant. In other words, participants are more likely to opt for an efficient allocation when the effect they have on others' payoff is more salient. In contrast, individual choices are significantly less efficient in an anonymous partner selection setting.

In the other columns of Table 5 we disaggregate the result and regress the efficient choice dummy on treatment for each of the three payoff categories separately. The results indicate that the T1 and T2 are associated with more efficient choices for both high and middle payoff participants. For low payoff participants, the treatment effect is not significant although, in terms of average efficiency across all treatments, low payoff participants are not statistically different from other payoff categories. It appears that an anonymous partner selection setting enables higher payoff participants to behave in a more selfish manner while in treatments T1 and T2 they may feel

moral pressure to behave altruistically towards lower payoff participants. In contrast, low payoff participants do not seem to have this concern, perhaps because they feel more entitled to pursue their self-interest, having been assigned to the lowest payoff category at the onset of the experiment.

### 3.2 Preference archetypes

In this subsection we adopt a more structural approach and assign participants to archetypes summarizing the form of their other-regarding preferences. We test whether this assignment varies with treatment. The idea behind the approach is that people behave in ways that may vary with the decision context, and that their behavior can be approximated by preference archetypes. If we know what archetypes best capture the behavior of a large fraction of the population in a given environment, we may be in a better position to predict what types of behavior to expect in that environment.

Scenarios were designed to facilitate the assignment of participants to the six different archetypes listed below (Charness and Rabin 2002, Cooper and Kagel 2013). These archetypes were chosen because they are easily identified within the framework of our experiment.

1. *Selfish*: A selfish player is defined as someone who maximizes  $\pi_i$ .
2. *Efficient*: An efficient player is someone who maximizes  $\bar{\pi}_i = \sum_{j \in N_i} \pi_j$ .
3. *Equity only*: Choose the allocation that minimize absolute inequality defined as  $\sum_{j \in N_i} |\pi_j - \bar{\pi}_i|$
4. *Spiteful*: Choose the allocation that maximizes one's relative payoff  $\pi_i - \frac{1}{3} \sum_{j \neq i, j \in N_i} \pi_j$
5. *Maximin*: Choose the allocation that maximizes the minimum payoff among the four affected individuals  $\max \min \pi_j, j \in N_i$ .
6. *Homophily*: Choose a partner from one's own type (high or low)

We seek to assign each participant to the archetype that best describe their behavior in the six rounds. Different participants may follow different archetypes. We start by identifying participants who follow a single archetype perfectly over all six rounds, and we observe what proportion of

participants we can assign in this manner. For high payoff types, payoffs are such that assignment is typically unambiguous. For low types, the choices made by a given subject may be consistent with more than one archetype, depending on the set of six scenarios they faced. Next, we then introduce the possibility of deviations from the behavior predicted by a single archetype. At the end of the section, we allow for the possibility of hybrid preferences.

In Table 6 we present the result of our first calculation. For each archetype  $k$ , we calculate  $\Delta u_i^k \equiv u_k(\pi_i^h) - u_k(\pi_i^l)$  where preference function  $u_k(\cdot)$  is that corresponding to archetype  $k$ . For each subject we then count the proportion of rounds (out of a maximum of 6) for which the subject behaves in accordance to archetype  $k$ , that is, for which  $y_i = 1$  if  $\Delta u_i^k > 0$  and  $y_i = 0$  if  $\Delta u_i^k < 0$ . We ignore cases in which  $\Delta u_i^k = 0$  because they are uninformative. We say subject  $i$  makes choices consistent with archetype  $k$  if this proportion is 100%. Depending on scenarios and player type, choices made over six rounds may be consistent with more than one archetype.

Results indicate that the archetype most consistent with observed choices is the ‘selfish’ utility model in which people only care about their material payoff. We do, however, observe systematic differences across treatments and types. Fewer participants are assigned to the selfish archetype in treatment T1 than in other treatments. The difference is strongest for high types, confirming earlier results that suggest these participants behave in a less selfish manner when the experiment is framed as an allocation process rather than as partner selection. Low types tend to behave more in accordance to the selfish archetype than high types, again confirming earlier results.

Turning to other archetypes, we note that very few participants are assigned to the efficiency only archetype, that is, have a utility function that would lead them to always choose the most efficient allocation. We do, however, note that the efficiency only archetype is more common in treatment T1, and among high types. This is consistent with some of our earlier findings that suggest efficiency concerns among some participants, but it reminds us that ‘efficiency only’ is not a suitable description of the way participants behave on average.

A small proportion of participants behave in agreement with the equity only archetype. This archetype assumes that participants always choose the allocation that results in the smallest level

of payoff inequality. This archetype is found mostly among low types for whom this overwhelmingly coincides with self-interest (100% overlap in choices between the two archetypes for low  $A$  types and 91% overlap for low  $M$  types).

A larger proportion of participants fit the invidious or spiteful archetype, that is, make choices that minimize the difference between their payoff and that of others. This archetype is found most often among participants to treatment T3, in line with earlier results emphasizing that the anonymous partner selection treatment seems to encourage invidious choices relative to the other two treatments. Caution is however warranted because 89% of the low  $M$  types whose decisions fit the invidious archetype also fit the selfish archetype.

A non-negligible proportion of low  $A$  types follows maximin preferences, i.e., they make choices that maximize the minimum payoff to any player. Since low  $A$  types nearly always are those players getting the minimum payoff, the data shows that maximin always coincides with self-interest for low  $A$  types. Overlap is also common (90%) among low  $M$  types. Hence this finding should not be given too much weight. Finally, contrary to other experiments that have documented that participants naturally assort according to randomly assigned type (e.g., Currarini and Mengel 2012), we find very little evidence of homophily in our data: very few participants systematically choose a partner of their type, i.e., low with low or high with high.

At the bottom of the table we report the proportion of participants who were assigned to multiple archetypes, and those whose behavior does not fit any. The last panel of Table 5 confirms that, by experimental design, high types can nearly always be unambiguously assigned to a single archetype. We were unable to do the same for low types because, with six rounds and four players, there were not enough degrees of freedom in the experiment to design scenarios that are sufficiently informative for both high and low types. This too is confirmed in Table 5. Multiple assignment is most common among low  $A$  types, a point that has already been touched upon in the earlier presentation.

The last row of Table 6 indicates that a sizeable proportion of participants do not fit any of the six archetypes we considered. Lack of fit is most noticeable in treatment T1, and this is true

for all payoff categories. The behavior of participants in this treatment is less well explained by the simple preference models we considered. But in all treatments there is a sizeable minority of participants whose behavior is not consistent with any of the archetypes we considered.

One possible explanation for this is that people make mistakes: they may have preferences that follow one of our archetypes but, due to inattention or lack of interest, they sometimes make choices that do not correspond to their underlying preferences. To investigate this possibility, we estimate a mixed maximum likelihood model. The starting point of the estimation methodology is the observation that:

$$\Pr(y_i = 1|\pi_i, \pi_{j \neq i}, T_i) = \sum_{k=1}^K \Pr(y_i = 1|\pi_i, \pi_{j \neq i}, T_i, k) \Pr(u = u_k|T_i) \quad (2)$$

where  $\pi_i$  and  $\pi_{j \neq i}$  denote the four payoffs potentially entering the preference utility  $u_k$  of archetype  $k = \{1, \dots, K\}$ . Since  $\pi_i$  and  $\pi_{j \neq i}$  are randomly assigned in the experiment, we can ignore correlation between payoffs and preferences. But we allow preferences to differ across treatments, hence the conditioning on  $T_i$ . A similar probability can be derived for  $y_i = 0$ . Since, for a given treatment  $T_i$ ,  $\Pr(u = u_k|T_i)$  is a constant, we denote it as  $\gamma_{kT}$ .

Next we assume that the probability of choosing action  $y_i = 1$  increases in  $\Delta u_i^k$ , the utility gain from choosing  $y_i = 1$  that is associated with payoffs  $\pi_i$  and  $\pi_{j \neq i}$  when preferences are given by  $u_k(\cdot)$ . To formalize this idea, we borrow from Luce (1959) and write:

$$\Pr(y_i = 1|\pi_i, \pi_{j \neq i}, T_i, k) = \frac{e^{\sigma_T \Delta u_i^k}}{1 + e^{\sigma_T \Delta u_i^k}} \quad (3)$$

Parameter  $\sigma_T$  captures how sensitive decisions are to  $\Delta u_i^k$  in treatment  $T$ . If  $\sigma_T = 0$ , the choice between  $y_i = 0$  and  $y_i = 1$  is random and does not depend on payoffs. If  $\sigma_T$  is arbitrarily large, expression (3) tends to 1 if  $\Delta u_i^k > 0$  and to 0 if  $\Delta u_i^k < 0$  – which corresponds to the case where choices are perfectly predictable once we know someone’s archetype and the payoffs they face. Intermediate values of  $\sigma_T$  capture situations in which participants systematically diverge from random play in the direction predicted by archetype  $k$ . The model assumes that participants are more likely to take the decision predicted by their archetype the larger the utility gain  $\Delta u_i^k$  is

between the two choices. In other words, participants make more mistakes when the difference in payoff is small. Mixed models of this kind have successfully been fitted to experimental data (e.g., Andersen et al. 2008, Null 2012).

The likelihood function has the form:

$$L(\gamma_k, \sigma | y_i, \{\Delta u_i^k\}, T_i) = \sum_{k=1}^K \gamma_{kT} \left( \frac{e^{\sigma_T \Delta u_i^k}}{1 + e^{\sigma_T \Delta u_i^k}} y_i + \frac{1}{1 + e^{\sigma_T \Delta u_i^k}} (1 - y_i) \right) \quad (4)$$

and is estimated separately for each treatment, ensuring that  $0 < \gamma_{kT} < 1$  and imposing that  $\sum_{k=1}^K \gamma_{kT} = 1$ .<sup>8</sup> Once  $\sigma_T$  and  $\{\gamma_{1T}, \dots, \gamma_{KT}\}$  have been estimated, we compute, for each subject, the posterior probability that their choices follows a particular archetype.<sup>9</sup> Accumulating across rounds for each individual  $i$ , we get the posterior probability that  $i$  follows archetype  $k$ :

$$\Pr(k | \{y_i\}) = \frac{\Pr(k) \Pr(\{y_i\} | k)}{\Pr(\{y_i\})} \quad (5)$$

where  $\{y_i\} = \{y_i^1, y_i^2, \dots, y_i^6\}$  is the set of decisions made by  $i$  over the six rounds. Since  $\hat{\gamma}_{kT}$  and  $\hat{\sigma}_T$  vary across treatment,  $\Pr(k | \{y\})$  also varies across treatment for the same set of choices made. Once we have  $\Pr(k | \{y\})$  for each subject, we look at how accurate the predictions are for different individuals, i.e., how accurately they are estimated to follow a given archetype.

Estimates of posterior probabilities are summarized in Table 7. The first panel of the Table reports the average of estimated posterior probabilities (5) calculated using parameters  $\hat{\gamma}_{kT}$  and  $\hat{\sigma}_T$  estimated using (4). The second panel of the Table assigns each individual to an archetype if their  $\Pr(k | \{y_i\})$  exceeds 0.5 for one  $k$  – which can happen at most for one  $k$ , but could happen for none. As it turns out, all our participants are assigned to one archetype, which suggests that the

---

<sup>8</sup>Estimation is achieved by numerical optimization in Stata. To ensure that all  $\Delta u_i^k$  have the same weight in the estimation, we normalize them to all have a unit standard deviation. Convergence difficulties can arise when  $\gamma_{kT} \approx 0$  for some  $k$ , or when the  $\Delta u_i^k$  are too correlated across archetypes (akin to multicollinearity).

<sup>9</sup>Let  $\Pr(k | y_i = 1)$  denote the probability that individual  $i$  is of archetype  $k$  if he/she sets  $y = 1$ . The starting point of our calculation is the following relationship that holds for each choice  $i$  makes:

$$\begin{aligned} \Pr(k | y = 1) &= \frac{\Pr(k) \Pr(y = 1 | k)}{\Pr(y = 1)} \\ &= \frac{\Pr(k) \Pr(y = 1 | k)}{\sum_k \Pr(k) \Pr(y = 1 | k)} \end{aligned}$$

For simplicity of exposition, we have omitted the dependence on  $\pi$  and  $T$ . Unconditional probability  $\Pr(k)$  is estimated by  $\hat{\gamma}_{kT}$  while  $\Pr(y = 1 | k)$  is obtained from expression (3) using estimated  $\hat{\sigma}_T$ .

method was able to infer everyone’s type with accuracy.<sup>10</sup> We do, however, note that the estimated value of  $\hat{\sigma}_T$  is smallest for treatment T3 ( $\hat{\sigma}_{T_3} = 6.60$  with a  $t$ -value of 5.59), intermediate for T2 ( $\hat{\sigma}_{T_2} = 14.48$  with a  $t$ -value of 4.25) and largest for T1 ( $\hat{\sigma}_{T_1} = 255.29$  with a poorly estimated  $t$ -value). This suggests that participants fit one of the six archetypes better in T3 than in T1. This confirms that we are less able to predict individual behavior in T1, perhaps because participants’ choices reflect preferences other than our six archetypes – more about this later.

We find that most participants fit the selfish archetype best. This is true for all treatments and all player types. Secondly, high types are systematically more likely to act selfish in partner selection treatments, particularly T3. This confirms earlier results. Third, participants with the lowest average payoff (low  $M$  types) overwhelmingly play selfish, even in the pie allocation treatment. This too is consistent with earlier observations. Fourth, the proportion of players classified as maximizing efficiency increases as we move from treatment T3 to T1. This is particularly noticeable for high types, mirroring earlier observations. But only a small proportion of players are best described as following this archetype.

Fifth, a number of players are classified as having spiteful preferences, that is, as choosing strategies that reduce the difference between their payoff and that of others even if it means reducing their own payoff. (If they had chosen to maximize their own payoff, they would have been classified as selfish, not spiteful.) The proportion of spiteful is highest in treatment T3, especially among low types. This findings is also in agreement with earlier results.

Finally, we find that a number of low types, especially those in the intermediate payoff category A, are classified as maximin players. This happens more frequently in treatment T1, suggesting that players in that treatment have some equity concerns, but these are not adequately captured by the equity only archetype – which only fits a small number of participants overall, and none of them in treatment T1. Equal pie sharing thus does not appear to be the top priority for any of the participants.

---

<sup>10</sup>In fairness, we should point out that we do not correct predicted archetypes for sampling error in parameter estimates. But given how strong assignment is, introducing the correction, if it were possible, would not greatly modify our results.

As robustness check, we also investigate a hybrid model that combines own payoff with an other-regarding preference  $u_i^m$  and estimate regressions of the form:

$$\Pr(y_i = 1) = \alpha_0 + \alpha_1 \Delta\pi_i + \alpha_i (\Delta\pi_i)^2 + \beta_1 \Delta u_i^m + \beta_2 (\Delta u_i^m)^2 + \beta_3 \Delta\pi_i \Delta u_i^m + \varepsilon_i \quad (6)$$

where  $\Delta\pi_i$  and  $\Delta u_i^m$  represent the material payoff and utility gain associated with choice  $y_i = 1$ , respectively. As before, all  $\Delta u_i^m$  are normalized to have the same unit standard deviation. Model (6) is estimated with preference archetypes (2) to (6) above as well as with altruistic preferences and with inequality aversion.<sup>11</sup>

For archetypes, the results, not shown here to save space, confirm earlier findings: efficiency considerations are significant in T2 and especially T1; invidious preferences are significant in treatment T3; maximin and equity-only preferences appear with the wrong sign, especially in treatment T1, a finding that is consistent with spiteful preferences; and there is little evidence of homophily. Results regarding altruistic preferences are contrasted. In treatment T3 altruism has the wrong sign, a result consistent with spiteful preferences. But in treatments T2 and especially T1,  $\Delta u_i^m$  becomes positively significant while  $\Delta\pi_i$  no longer is. This suggests that altruist preferences do a reasonably good job of predicting participants' choices in T2 and T1 – but not in T3. In contrast, inequality aversion  $\Delta u_i^m$  is either statistically non-significant, or appears with the wrong sign. How much weight we should ascribe to the latter findings is unclear, given that the experiment was not designed to test altruism or inequality aversion directly, and so has little power.<sup>12</sup>

## 4 Discussion and conclusions

We have reported on an experiment designed to test whether people exhibit different other-regarding preferences depending on whether the choices they make are framed as an allocation problem or a

<sup>11</sup>For altruist preferences, we set  $u_i \equiv \ln(\pi_i) + 0.5 \ln(\pi_{-i})$  where  $\pi_{-i} \equiv \sum_{j \neq i, j \in N_i} \pi_j$ . Parameter value 0.5 captures an intermediate level of altruism. For inequality aversion we follow Okada and Reidl (2005) and posit a utility function of the form

$$u_i^{10} \equiv \ln(\pi_i) - \frac{1}{2} \sum_{j \neq i, j \in N_i} |\ln(\pi_i) - \ln(\pi_j)|^- - \frac{1}{3} \sum_{j \neq i, j \in N_i} |\ln(\pi_i) - \ln(\pi_j)|^+$$

and vary  $N_i$  to include either only  $i$ 's partner or the three individuals affected by  $i$ 's choice.

<sup>12</sup>The coefficient of correlation between  $\Delta\pi_i$  and  $\Delta u_i^m$  exceeds 0.9 for altruist preferences and each inequality aversion measure we tried.

partner selection problem and depending on the size of the group involved in the decision.

We find that when choices are framed as a partner selection problem instead of a pure allocation problem, agents are less likely to sacrifice their own material well-being to increase the well-being of others – but more willing to sacrifice a higher payoff to reduce the difference between their payoff and that of others. Similarly, they behave more selfishly if they are in a larger group setting.

These findings are broadly consistent with the literature on inequality aversion (e.g., Fehr and Schmidt 1999, Okada and Riedl 2005), but with a twist. Experimental subjects with a higher than average payoff exhibit some altruism or concern for efficiency, but more so in treatments are couched as an allocation problem or a choice of partner in a small group. When asked to select a partner in a large anonymous setting, high payoff players no longer display any sign of altruism and simply maximize their own material payoff. In contrast, subjects with the lowest average payoff display no altruism or concern for efficiency in the small group setting, but exhibit spiteful preferences in a large anonymous setting. In other words, we get the two ‘sides’ of inequality aversion (altruism and spite), but not in the same setting.

These findings raise a number of issues. Fafchamps (2011) argues that economic development requires a change in allocation processes away from allocation within the household or extended family to allocation within markets or within hierarchical organizations. This transformation requires a change in social norms from risk sharing in long-term gift exchange to contract compliance in an anonymous market setting. In a gift exchange allocation process, efficiency requires that individuals make choices that are altruistic or efficiency-seeking. In market exchange, efficiency can be achieved through competition alone; altruistic or efficiency-seeking behavior is not required. To the extent that the behavior of our experimental subjects can be interpreted as reflecting context-specific norms, they fit this pattern to a large extent. We do, however, also find that less fortunate participants occasionally select a partner so as to prevent them from achieving a higher payoff. It is unclear whether competition is sufficient to counter the inefficiency produced by such choices. More research is needed.

The findings also raise a more fundamental question: Why, even with minimal contextualization,

do human subjects respond the way they do to differences in the frame in which choices are made? Is it possible that the human brain processes moral choices in a way that systematically reduces altruism and reinforces spite in an anonymous partner-selection setting relative to a small group setting?

The literature on trolley experiments (e.g., Greene 2012) suggests one possible avenue of enquiry so far ignored by economists, namely that people feel less guilty about the consequences of their actions when these consequences seemingly depend on mechanical devices, random events, and choices made by others.<sup>13</sup> If correct, this interpretation suggests that markets – and partner selection problems in large populations – blunt other-regarding preferences by diluting the perceived effect that actions have on the welfare of others, thereby eliciting less guilt for failing to follow norms of acceptable behavior that apply in small groups. We offer in Appendix 2 a simple model of such preferences.<sup>14</sup> Further work is needed on the origin of other-regarding preferences, and especially the extent to which they are shaped by the decision environments over which altruistic norms apply.

---

<sup>13</sup>Mikhael (2011) goes so far as to suggest that this is because the human brain processes moral choices of cause and effect by applying syntactic rules. This means that ‘pushing the man to his death’ generates more guilt than ‘pushing the button that activates the lever that opens the door that pushes the man to his death’ even though the ultimate consequence is the same.

<sup>14</sup>The difference between treatments T2 and 3 similarly is in the *process* by which payoff are generated, not in the actual payoffs themselves. Dilution as defined here can thus be seen as a situation in which people’s preferences depend not just on payoffs but also on the way these payoffs are obtained. If this interpretation is correct, this paper can be seen as following in the footsteps of Charness and Rabin (2003) who demonstrated that people have preferences over process, not just final outcomes.

## 6 Appendix 1. Experimental protocol

We consider three different versions of the second stage. The first is the "*partnership formation in large groups*" version, whereby participants are organized in groups of 24 divided equally into  $A$  and  $M$  categories. participants are asked to choose a partner type from the other category . If their choice is implemented, we randomly match them with one of the 12 people from the other category. The second version is the "*partnership formation in small groups*" version, whereby participants are put in groups of 4 (a high and a low type in the  $A$  category and a high and a low type in the  $M$  category). participants are asked to choose whether they would like to form a partnership with the high or low type in the other category. The last version is the "*earnings division in small groups*" version whereby participants are not asked to choose a partner, but are simply asked to choose between two divisions of earnings between four players. The scenarios we propose in these three treatments are perfectly equivalent in terms of their implications for efficiency and income distribution. The only variation is the salience of these implications. Importantly, we provide the same information in all treatments.

### **Treatment T3 - Partnership formation - large groups**

Here each participant is asked to report whether they would prefer forming a partnership with a low or high type from the other category. The scenarios are presented on an answer sheet (see appendix 1). They are shown the distribution of earnings associated with the four different types of partnership (high  $A$  - high  $M$ , low  $A$  - low  $M$ , high  $A$  - low  $M$ , and low  $A$  - high  $M$ ), including those that do not involve them. These choices are illustrated graphically with coloured pies. The size of the pie represents the total earnings to be shared. Each earnings division corresponding to each partnership is represented with a pie division. Participants are asked to tick one of two boxes (top 50% or bottom 50%) at the bottom of the answer sheet.

The partnership formation is implemented as follows. One of the categories ( $A$  or  $M$ ) is chosen randomly ex-post to be the leader in partnership formation (which means that the partnerships will be implemented according to their reported preferences, irrespectively of the reported preferences

made by participants in the other category). If there is more demand for one type than is available, then the scarce type is allocated in a random manner between those who have expressed a preference for it.

Table 2 describes the different parameter configurations corresponding to the different situations. Note that the payoffs are not always symmetric for low types. To be able to distinguish between selfish preferences and maximin payoff, we designed a situation where the payoff of the low type individual is not the minimum payoff. In those situations, the gains from partnership are not shared equally between the  $A$  and  $M$  partners. The addition partner gets a larger share. In those cases, a low  $A$  type who wishes to maximise the minimum payoff would choose a high  $M$  type, while if she wishes to maximise her own payoff, she would choose a low  $M$  type.

### **Treatment T2 - Partnership formation - small groups**

In the second treatment, participants are told that they are randomly allocated in groups of 4, composed of 2 people who did the multiplication task (one high, one low) and 2 people who did the addition task (one high, one low). They are asked again whether they would prefer forming a partnership with a low or high type from the other category. The scenarios are presented on an answer sheet (see appendix 1) in a manner similar to treatment 1, except that we now write explicitly the implication of the partnership decision for the other people in the group. They are asked to tick one of two boxes (top 50% or bottom 50%) at the bottom of the answer sheet (see Appendix 1)

### **Treatment T1 - Earnings division**

In treatment participants are told that they are randomly allocated in groups of 4, composed of 2  $M$  participants (one high and one low) and 2  $A$  participants (one high and one low). They are asked to choose between two distributions of earnings that correspond to the earnings distribution in T3 and T2 (see Appendix 1). Each earnings distribution is represented by a pie division. The main difference with T3 and T2 is that to each choice is associated a single pie that represents the division of earnings between the *four* people in the group, instead of two pies for each of the two partnerships. Thus, the implication of the decision for efficiency and income distribution is most

salient in this last treatment. This treatment is also the closest to the dictator game designs used in the literature on social preferences (references...).

## 7 Appendix 2. Dilution

In this appendix we illustrate how altruism can become diluted in an anonymous partner-selection setting.<sup>15</sup> The trolley experiments (e.g., Greene 2012, Mikhael 2011) suggest that people feel less guilt when the consequences of their action involve mechanical devices, random events, or choices made by others. This suggests that, say, pushing an anonymous person to their death generates more guilt than pushing a button that randomly selects one of  $M$  anonymous persons to be pushed to their death. A similar contrast characterizes the difference between treatments T2 and T3: selecting in T2 a partner that leaves other experimental subjects a lower payoff may generate more guilt than indicating in T3 a preference for a partner type that, de facto, removes one partnership from the choice set of others and has similar consequences on randomly selected individuals.

To illustrate how this idea can be formalized, we construct preferences in which individuals value the consequence of their action on others differently depending on whether they affect, with certainty, one person or one of  $M$  randomly selected individuals. Let  $W_2(h)$  denote the utility gain from choosing a ‘high’ partner  $h$  instead of a ‘low’ partner  $l$ . Consider treatment T2 and let this choice be efficient, so that for a subject with sufficiently altruistic preferences, we have:

$$W_2(h) \equiv \pi_i^h - \pi_i^l + \beta \sum_{j \neq i, j \in N_i} (\pi_j^{h_i} - \pi_j^{l_i}) > 0$$

where  $\beta \leq 1$  is a parameter capturing the strength of altruism,  $N_i$  is the set of four subjects that includes  $i$ , and  $\pi_j^{h_i} - \pi_j^{l_i}$  is the effect that player  $i$  has on the payoff of player  $j$  in  $N_i$  when choosing  $h$ .

In treatment T3, the effect on the payoff of others is essentially the same as in treatment T2 but  $i$  does not know which exact players will be affected. The expected efficiency gain from choosing a

---

<sup>15</sup>More sophisticated models can be written – e.g., models in which subjects have preferences on whether they interfere or not with other subjects’ choices – but they would take us too far from the object of this paper, which is primarily empirical.

partner  $h$  can now be written:

$$W_3(h) \equiv \pi_i^h - \pi_i^l + \beta \sum_{j \neq i, j=1}^{24} E[\pi_j^{h_i} - \pi_j^{l_i}]$$

Realized payoffs are as in treatment T2, but the identity of the three individuals affected by  $i$ 's decision has not yet been determined. It is this difference that opens the door to a possible dilution effect as follows.

Let us first consider  $i$ 's randomly assigned partner and, without loss of generality, assume that this person belongs to category  $M$ . The effect of  $i$ 's choice on this person's payoff is  $\pi_j^{h_i} - \pi_j^{l_i}$ ; other possible high  $M$  partners are unaffected by  $i$ 's decision so that for them the effect is 0. The total effect of  $i$ 's choice on the expected payoff of high  $M$  subjects is thus:

$$\sum_{j=1}^6 E[\pi_j^{h_i} - \pi_j^{l_i}] = \sum_{j=1}^6 \frac{1}{6} (\pi_j^{h_i} - \pi_j^{l_i}) = \pi_j^{h_i} - \pi_j^{l_i} \quad (7)$$

Similar calculations can be done for subjects in the other two category  $\times$  type groups. We get:

$$W_2(h) = W_3(h)$$

which predicts that, in the absence of dilution, individuals should make identical decisions under treatments 2 and 3.

Let us now introduce a dilution parameter  $\alpha \geq 1$  and rewrite (7) as:

$$\sum_{j=1}^6 E^\alpha[\pi_j^{h_i} - \pi_j^{l_i}] = \sum_{j=1}^6 \left(\frac{1}{6}\right)^\alpha (\pi_j^{h_i} - \pi_j^{l_i}) \leq \pi_j^{h_i} - \pi_j^{l_i} \quad (8)$$

with strict inequality if  $\alpha > 1$ . The effect on the other two category  $\times$  type groups can be handled in the same way. Equation (8) is equivalent to positing that individuals underweigh the probability that they affect other players, and is formally similar to probability weighting in prospect theory.

With  $\alpha$  large enough,  $\sum_{j=1}^6 \left(\frac{1}{6}\right)^\alpha (\pi_j^{h_i} - \pi_j^{l_i})$  tends to 0 and we have:

$$W_3(h) = \pi_i^h - \pi_i^l$$

which corresponds to selfish preferences: with enough dilution, people no longer take into account any efficiency cost they impose on others, and pursue their own material welfare only.

## 8 Appendix 3. Accomodation vs dilution

At first glance it appears that treatments 2 and 3 are different in the sense that, in treatment 3, how my choice affect others depends on the actions of others while in treatment 2 it does not. This turns out to be largely an illusion, however, even if showing this rigorously is rather intricate. Although nothing of importance hinges on this issue for our results, we discuss it here in some detail, lest it become a distraction for the reader.

We first show that, if players have the same preferences, treatment 2 and 3 are identical in the sense that my choice affects three (yet to be determined ) other players. We then allow for the possibility that players have different preferences, and we introduce the concept of accommodation. Finally we show that, in expectation, there is, if anything, more accommodation in treatment 2 as in treatment 3.

### 8.1 The intuition

Since all subjects in treatment 3 play the same scenario, players in the same category ( $A$  or  $M$ ) and type (high or low) face the same payoff structure. It follows that, if they all have the same preferences, they should make the same choice. If they make the same choices, the impact on others' payoffs in treatment 3 is the same as in treatment 2: if I take an attractive partner for myself, this attractive partner is not available to someone else and, at the margin, this forces two other players into a less profitable pairing. The only difference is that, in treatment 3, the identity of these players is determined by chance after I have made my choice while in treatment 2 the identity of these players is determined by chance before I have made my choice. Since the identity of other players is never revealed, the two should be equivalent – except for the dilution effect (see Appendix 2).

If we allow players to have different preferences, I could delude myself into thinking that, while I am acting to maximize my own payoff, others are not – in which case my choice may be *accommodated* by the unselfish choice of others. In other words, I could hope to free ride on

another player's altruism.<sup>16</sup> Consequently, in treatment 3 subjects may convince themselves that they are only affecting one participant's payoff as long as there exists other players who exactly complement their choice. Because players face the same payoff structure, such beliefs are largely wishful thinking: why would I be the only one who is selfish. But accommodation opens the possibility that players make choices based on their beliefs about how others play.

It therefore appears that how people play in treatment 3 depends on expectations about others' actions while in treatment 2 it does not. This is, however, where the optical illusion resides. When a player acts selfishly in treatment 2, he may similarly convince himself that others in his group would accommodate his choice – so that he has no determinant effect on the payoffs of other players because these players would accommodate his choice. To illustrate, imagine two grooms and two brides, as in treatment 2. Groom 1 selects the handsomest bride for himself, *de facto* forcing the other groom to pair with the less desirable bride. Yet groom 1 can convince himself that this is precisely the bride that groom 2 would have selected, no matter how unlikely this possibility may be. In other words, in both treatments 2 and 3 subjects can delude themselves that others will make choices that render their own decision unconstraining.

Having presented the argument in an intuitive manner, we now offer a slightly more rigorous treatment of accommodation, while discussing its relationship with the dilution hypothesis. To recall, we define dilution as the property by which people put less weight on affecting two individuals each with probability 1/2 than on affecting one individual with probability 1. We define accommodation as expecting that other players will accommodate my selfish preferences so that I can pretend I did not deprive anyone and can ignore the consequences of my choices on others.

## 8.2 Accommodation

To formalize the above intuitive argument, we need to distinguish between what  $i$ 's preferences are with respect to others' payoff and the realization that other individuals may choose something else than what  $i$  would choose in their place, that is, the possibility that others playes have different

---

<sup>16</sup>Or, alternatively, I could hope that my altruism is accommodated by someone else's selfishness.

preferences. To demonstrate this, without loss of generality we examine what is  $i$ 's gain from playing high instead of low:

$$\begin{aligned} W_3^i(h) &\equiv \pi_i^{h_i} - \pi_i^{l_i} + \beta \sum_{j \neq i, j=1}^N E[\pi_j^{h_i} - \pi_j^{l_i}] \\ &= M_i^i + \beta \sum_{j \neq i, j=1}^N E[M_j^i] \end{aligned}$$

where  $\pi_j^{h_i}$  is the payoff to  $j$  if  $i$  chooses to play high,  $\pi_j^{l_i}$  is  $j$ 's payoff if  $i$  plays low,  $N$  is the number of players in the game and  $M_j^i \equiv \pi_j^{h_i} - \pi_j^{l_i}$ .

The whole issue is how  $E[M_j^i]$  is calculated. To illustrate how this matters, we now assume that the rules of the game with 24 players apply but we vary  $N$ . We focus on  $i$  assuming his choice is selected first.

First consider the case where  $N = 4$ . There are three other players apart from  $i$ . Let  $m$  be the partner selected by  $i$  and let  $k$  be the player of the same category ( $A$  or  $M$ ) as  $i$  but of the opposite type. In treatment 3, the choices of  $i$  and  $k$  are first collated. If  $i$  chooses high and  $k$  chooses low, then both their choices are accommodated. Hence player  $i$  only directly affects the payoff of the high player in the other category. In contrast, if  $i$  and  $k$  choose high, only one of them can have their choice. Imagine that  $i$ 's choice is selected. In this case, his choice determines the payoffs of all four players. This examples shows that  $i$ 's choice only affects three other players if  $k$  does not accommodate his choice.

Let us now assume that  $k$  accommodates  $i$ 's choice (i.e., chooses low) with probability  $p$ . We have:

$$W_3^i(h) = M_i^i + \beta M_m^i + p\beta 0 + (1-p)\beta \sum_{j \neq i, m, j=1}^N E[M_j^i]$$

We immediately see that treatment 3 creates a 'dilution' effect: when player  $k$  accommodates  $i$ 's choice,  $i$  can imagine that his choice has no effect on  $k$  and that the player  $k$  chooses. In other words, whatever effect  $i$ 's choice has on players  $k$  and his partner can be 'blamed' on  $k$ 's choice, not on  $i$ . Note that this dilution effect may be there in treatment 2 as well, depending on  $i$ 's thought process. The key idea is that  $i$  can blame someone else for some of the choices made, and this

reduces the sense of responsibility  $i$  feels for the effect of his choice on others.

This reasoning can be generalized to more players. For instance, consider the case in which  $N = 8$  and continue to assume that  $i$  plays high. There are three possible choice vectors for the other three  $k$  players:  $\{high, high, high\}$  which happens with probability  $(1-p)^3$ ,  $\{high, high, low\}$  which happens with probability  $p(1-p)^2$ ,  $\{high, low, low\}$  which happens with probability  $p^2(1-p)$ , and  $\{low, low, low\}$  which happens with probability  $p^3$ . We see that if the other three players accommodate  $i$ 's choice (i.e., the  $\{high, low, low\}$  case),  $i$  can imagine that his choice has no effect at the margin on  $k$  players (and hence on anyone except  $m$ ) since  $k$  players got their choice. In other cases,  $i$ 's choice has an effect at the margin but only with a certain probability.

### 8.3 A simple example

This probability can be calculated for a simple example. Imagine  $2N$  players asked to choose between two possible prizes, chocolate or marmite, each available in quantity  $N$ . Each player expresses a choice for one of them. Let  $M$  be the number of players who choose marmite. If there is excess demand for marmite, i.e., if  $M > N$ , the prizes are assigned at random (as is done in treatment 3) such that the probability of getting marmite is  $N/M$  for someone who chooses marmite. Similarly if  $M < N$ , chocolates are assigned at random. If  $M = N$  everyone gets their choice.

Now consider  $i$ 's choice and imagine that  $i$  derives disutility from preventing another player from getting his choice. For simplicity let this disutility be  $D$ . Similarly let  $-D$  be the utility player  $i$  derives from helping another player get his preferred choice. Without loss of generality, imagine that  $i$  prefers marmite and let  $i$ 's payoff in this case be  $\pi$ . Let other players' choices be  $M_i$ . If  $M_i = N - 1$  then  $i$  can get marmite without preventing anyone else from getting their choice. In this case,  $i$ 's payoff is  $\pi$ . In contrast, if  $M_i > N - 1$ , by choosing marmite, with probability 1 player  $i$  deprives one other player from getting their preferred choice. Hence  $i$ 's payoff is  $\pi - D$ . Similarly, if  $M_i < N$ , that is, if most other players do not like marmite, by choosing marmite  $i$  makes one other player happy with probability 1. Hence  $i$ 's payoff is  $\pi + D$ .

Now let  $p$  be the probability that other players like marmite. We have:

$$\Pr(M_i = N - 1) = \binom{2N - 1}{N - 1} p^{N-1} (1 - p)^N = \frac{(2N - 1)!}{N!(N - 1)!} (1 - p)[p(1 - p)]^{N-1}$$

since there are  $2N - 1$  players other than  $i$ . If  $N = 1$  (i.e., there are two players) the above boils down to:

$$\Pr(M_i = N - 1) = \Pr(M_i = 0) = 1 - p$$

With two players only, there is a non-negligible probability that  $i$ 's choice is accommodated by the other player. In contrast, if  $N$  is large, then  $\frac{M_i}{2N-1}$  tends to  $p$ . In this case, if  $p > 0.5$  player  $i$  knows that, with a very high probability, he is taking marmite away from people who like it while if  $p < 0.5$  he knows he is leaving chocolate for people who like it. In other words, if  $i$  has reasons to believe that  $p \neq 0.5$  then the larger the group is the more likely  $i$  is to affect someone else's choice.

If  $i$  believes that everybody likes marmite, or that everyone has the same taste as he does, then  $i$ 's expected utility is  $\pi - D$  while if he believes others dislike marmite, his expected utility is  $\pi + D$ . If other players' payoff is not a good but money, then player  $i$  would normally expect other players to prefer the choice that yields the highest monetary payoff for them. In our example, if marmite is a higher monetary payoff,  $p > 0.5$  and player  $i$  expects to take away from others' payoff.

It follows from the above reasoning that, in a large group where one choice is better for most other players,  $i$  expects to affect other players' payoff such that:

$$\begin{aligned} W_3(h|N = \infty) &\equiv \pi_i^h - \pi_i^l + \beta \sum_{j \neq i, j=1}^N E[\pi_j^{h_i} - \pi_j^{l_i}] \\ &\approx \pi_i^h - \pi_i^l + \beta \sum_{j \neq i, j=1}^N \frac{4}{N} (\pi_j^{h_i} - \pi_j^{l_i}) = W_2(h) \end{aligned}$$

In contrast, in a small group, say a group of 2,  $i$  could imagine that player  $k$  will accommodate his choice. This occurs with probability  $(1 - p)$ . Hence  $i$ 's utility then is:

$$W_3(h|N = 2) \equiv \pi_i^h - \pi_i^l + \beta(1 - p)0 + \beta p \sum_{j \neq i, j=1}^N E[\pi_j^{h_i} - \pi_j^{l_i}]$$

which is a *less* other-regarding preference, i.e., it is equivalent to a smaller  $\beta' = \beta p$ . This means that this kind of effect works in the opposite direction from dilution.

It is possible to show that *for any*  $p$ , the probability that other players accommodate  $i$ 's selfish choice *falls* with  $N$ . See stata do file binomial.do for an illustration. This means that, if anything, accommodation is *more* likely in treatment 2 than in treatment 3, so accommodation *cannot* be an explanation for dilution.

## 8.4 Conclusion

1. If others' payoff are monetary, then the utility of helping or hindering others' choices can be approximated by the effect on their payoff times a welfare weight  $\beta$ . This simplifies the notation to  $W_3(h|N)$ .
2. If there is a large group, then the choice of  $i$  is nearly never indifferent (i.e., it is nearly never accommodated) *unless*  $p = 0.5$  (or more precisely some unique value  $\frac{N-1}{2N-1}$  close to 0.5).
3. For groups of intermediate size (e.g.,  $N = 6$  as in treatment 3) the probability of accommodation is highest for  $p = \frac{N-1}{2N-1}$ .
4. For groups of smallest size ( $N = 1$  as in treatment 2) the probability of accommodation is  $1 - p$  and thus is 1 for  $p = 0$  and 0 for  $p = 1$ .
5. The probability of accommodation falls with group size: the larger the group, the lower the probability of accommodation is for any  $p$ .
6. If players form rational expectations about others' play, they will expect them to seek to improve their own payoff. Hence  $p \gg 0.5$  if marmite/high partner is a better choice for the majority of players in  $i$ 's category and type (who by design share  $i$ 's payoff structure). In this case, the probability of accommodation is low in all games.

The bottomline is that accommodation *cannot* explain dilution since it operates in the opposite direction.

Posterior probability of archetype based on mixed MLE model (see text for details). Parameters are estimated separately for each treatment.

Predicted archetype =1 if Pr(archetype)>0.5 and 0 otherwise.

**APPENDIX: EXPERIMENTAL INSTRUCTIONS**

**[Instructions treatment 1]**

**Centre for Experimental Social  
Sciences**

**EXPERIMENT  
November2011**

**INSTRUCTIONS**

**Please wait for the experimenter to indicate the start of the  
experiment. These instructions will be read aloud by the  
experimenter shortly.**

Dear participants,

Welcome and thank you for participating to this experiment. Before we describe the experiment, we wish to inform you of a number of rules and practical details.

### **Important rules**

- Your participation is considered voluntary and you are free to leave the room at any point if you wish to do so. In that case, we will only pay you the show-up fee of £4.
  - **Silence:** Please do remain quiet from now on until the end of the experiment. You will have the opportunity to ask questions in a few minutes.
- 

### **What will happen at the end of the experiment**

Once the experiment is finished, please remain seated. We will need around 10 minutes to prepare your payment. We will move to another room and you will be called up successively by the number on your table (please take it with you as you leave the lab); you will then receive an envelope with your earnings and you will be asked to sign a receipt.

---

## Description of the experiment

The experiment is structured in two stages. The first stage is called the [production stage](#), you will be asked to do a calculation task for 3 minutes. The second stage is called the [earnings division](#) stage, where you will be asked how to divide earnings between participants. Both stages are important in determining your final earnings.

### STAGE 1: PRODUCTION STAGE

Production here is achieved through two tasks: [Adding](#) and [Multiplying](#) numbers. Half of the participants will be asked to add numbers ("addition" task) and the other half will be asked to multiply numbers ("multiplication" task). The goal is to do as many calculations correctly as possible in 3 minutes. At the end of the 3 minutes, we will identify who are the TOP 50% best performers in each task and who are in the BOTTOM 50% performers in each task (that is, there will be ¼ of participants in the "TOP 50% multiplication", a ¼ in the "TOP 50% addition", a ¼ in the "BOTTOM 50% multiplication" and a ¼ in the "BOTTOM 50% addition").

### STAGE 2: EARNINGS DIVISION STAGE

In a second stage, you will be placed in groups of 4, each composed of

- A TOP 50% "multiplication" participant
- A BOTTOM 50% "multiplication" participant
- A TOP 50% "addition" participant
- A BOTTOM 50% "addition" participant

You will be asked to choose between two allocations of earnings that differ by

- (1) the total amount of earnings to be divided
- (2) how it is allocated between the four people in the group

We will present you with 6 scenarios. Each scenario corresponds to [different joint earnings](#) and [different ways of dividing these earnings](#). All the participants in the session will receive the same scenarios (and these will be numbered 1, 2, 3, 4, 5 and 6). You will have more than enough time (10 minutes in total) to study each of these scenarios carefully.

Please report your preferred choice in each scenario. You will simply need to tick one of the boxes at the bottom of the answer sheet.

After we have collected your answers for all 6 scenarios,

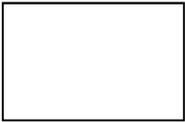

- One of these 6 scenarios will be selected at random
- For each group of four people, we will choose one person at random and implement her choice of allocation for the four people in her group.

Note that the first line of the answer sheet will inform you privately about whether your performance was in the TOP 50% or BOTTOM 50% of your own group.

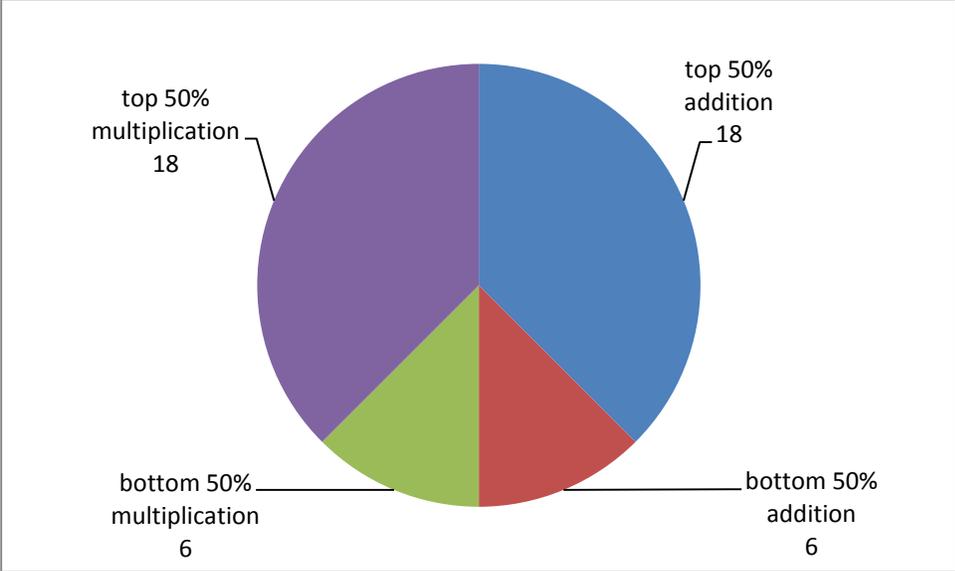

We show you on the next page an [example](#) of answer sheet.

The earnings are indicated in Experimental Currency Units. The exchange rate is £1=1.50 ECU.

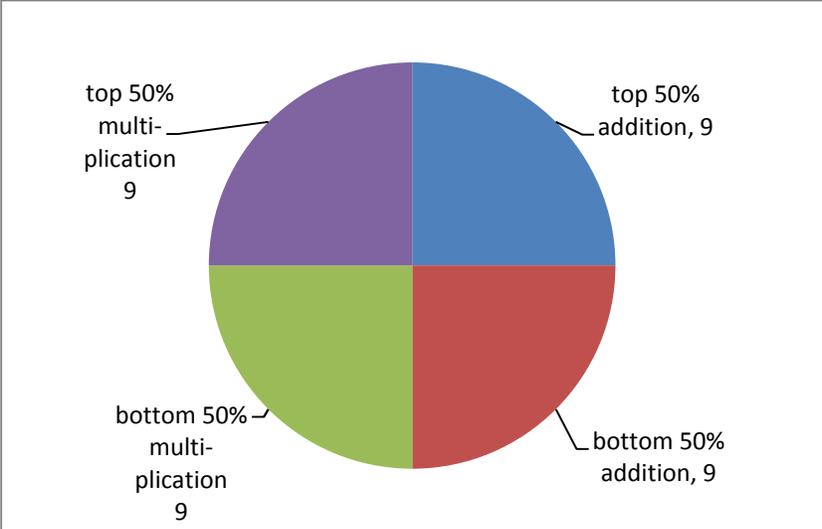

You did the **MULTIPLICATION** task.  
Your performance in the first round was in the **TOP 50%**

**POSSIBLE EARNINGS DIVISION 1: Total earnings 48**

**POSSIBLE EARNINGS DIVISION 2: Total earnings: 36**

**INDICATE (WITH A TICK) WHICH EARNINGS DIVISION YOU PREFER:**

- Earnings division 1
- Earnings division 2

At the very end, we will circulate a questionnaire that has no implications for your earnings. We would be grateful if you can fill it in carefully.

---

## Description of the experiment

The experiment is structured in two stages. The first stage is called the [production stage](#), you will be asked to do a calculation task for 3 minutes. The second stage is called the [partnership formation stage](#), where you will be asked with whom you would like to form a partnership. Both stages are important in determining your final earnings.

### STAGE 1: PRODUCTION STAGE

Production here is achieved through two tasks: [Adding](#) and [Multiplying](#) numbers. Half of the participants will be asked to add numbers ("addition" task) and the other half will be asked to multiply numbers ("multiplication" task). The goal is to do as many calculations correctly as possible in 3 minutes. At the end of the 3 minutes, we will identify who are the TOP 50% best performers in each task and who are in the BOTTOM 50% performers in each task (that is, there will be ¼ of participants in the "TOP 50% multiplication", a ¼ in the "TOP 50% addition", a ¼ in the "BOTTOM 50% multiplication" and a ¼ in the "BOTTOM 50% addition").

### STAGE 2: PARTNERSHIP FORMATION STAGE

In a second stage, you will be placed in groups of 4, each composed of

- A TOP 50% "multiplication" participant
- A BOTTOM 50% "multiplication" participant
- A TOP 50% "addition" participant
- A BOTTOM 50% "addition" participant

You will be asked to form a partnership with a person who performed a different task than yours (addition or multiplication). The joint earnings will depend on the performance of both partners in the first stage. More precisely, the joint earnings will depend on whether:

- Both are in the TOP 50%,
- One is in the TOP 50% and the other is in the BOTTOM 50%,
- Both are in the BOTTOM 50%.

We will give you a choice between forming a partnership with a person from the TOP 50% or with a person from the BOTTOM 50% in the other task. Each partnership will be associated with a given division of earnings in the group, which will be clearly indicated.

We will present you with 6 scenarios. Each scenario corresponds to [different joint earnings](#) and [different ways of dividing these earnings](#) in the group. All the participants in the session will receive the same scenarios (and these will be numbered 1, 2, 3, 4, 5 and 6). You will have more than enough time (10 minutes in total) to study each of these scenarios carefully.

Please report your preferred choice in each scenario. You will simply need to tick one of the boxes on the answer sheet.

After we have collected your answer sheet for all 6 scenarios,

- One of these 6 scenarios will be selected at random
- For each group of four people, we will choose one person at random and implement her choice. For example, if the person selected at random prefers to form a partnership with the person from the TOP 50% in the other task, then automatically the two people from the BOTTOM 50% will be matched to each other.

Note that the first line of the answer sheet will inform you *privately* about whether your performance was in the TOP 50% of BOTTOM 50% of your own group.

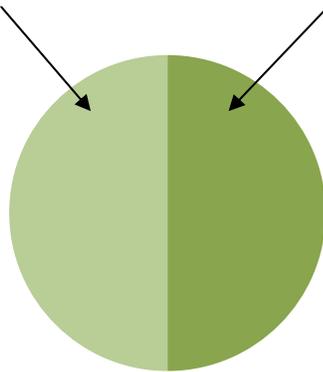

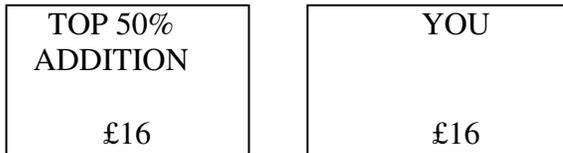

We show you on the next page an [example](#) of an answer sheet. You will have two answer sheets per page corresponding to 2 different scenarios.

You did the MULTIPLICATION task.  
Your performance in the first round was in the TOP 50%

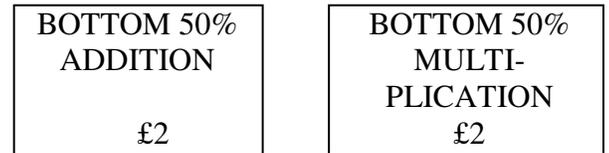

DIVISION OF EARNINGS IF YOU FORM A PARTNERSHIP WITH TOP 50% ADDITION

TOP 50% ADDITION  
& TOP 50% MULTIPLICATION (YOU)  
JOINT INCOME: £32

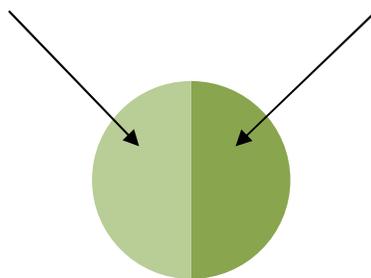

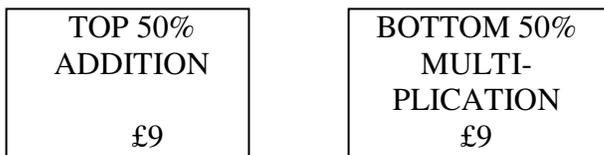

BOTTOM 50% ADDITION  
& BOTTOM 50% MULTIPLICATION  
JOINT INCOME: £4

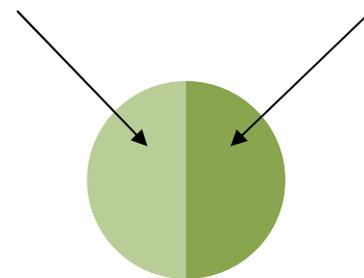

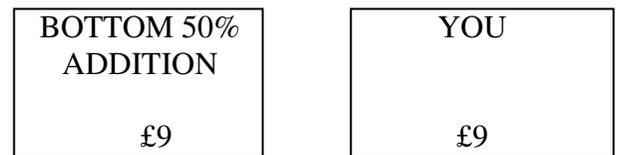

---

DIVISION OF EARNINGS IF YOU FORM A PARTNERSHIP WITH BOTTOM 50% ADDITION

TOP 50% ADDITION  
& BOTTOM 50% MULTIPLICATION  
JOINT INCOME: £18

BOTTOM 50% ADDITION  
& TOP 50% MULTIPLICATION  
JOINT INCOME: £18

Indicate (with a tick) with whom you would prefer to form a partnership:

- TOP 50% "ADDITION"
- BOTTOM 50% "ADDITION"

At the very end, we will circulate a questionnaire that has no implications for your earnings. We would be grateful if you can fill it in carefully.

Sciences**

**EXPERIMENT  
May 2011**

**INSTRUCTIONS**

**Please wait for the experimenter to indicate the start of the  
experiment. These instructions will be read aloud by the  
experimenter shortly.**

Dear participants,

Welcome and thank you for participating to this experiment. Before we describe the experiment, we wish to inform you of a number of rules and practical details.

### **Important rules**

- Your participation is considered voluntary and you are free to leave the room at any point if you wish to do so. In that case, we will only pay you the show-up fee of £4.
  - **Silence:** Please do remain quiet from now on until the end of the experiment. You will have the opportunity to ask questions in a few minutes.
- 

### **What will happen at the end of the experiment**

Once the experiment is finished, please remain seated. We will need around 10 minutes to prepare your payment. We will move to another room and you will be called up successively by the number on your table (please take it with you as you leave the lab); you will then receive an envelope with your earnings and you will be asked to sign a receipt.

---

## Description of the experiment

The experiment is structured in two stages. The first stage is called the [production stage](#), you will be asked to do a calculation task for 3 minutes. The second stage is called the [partnership formation stage](#), where you will be asked with whom you would like to form a partnership. Both stages are important in determining your final earnings.

### STAGE 1: PRODUCTION STAGE

Production here is achieved through two tasks: [Adding](#) and [Multiplying](#) numbers. Half of the participants will be asked to add numbers ("addition" group) and the other half will be asked to multiply numbers ("multiplication" group). The goal is to do as many calculations correctly as possible in 3 minutes.

At the end of the 3 minutes, we will identify in each group who are in the TOP 50% best performers and who are in the BOTTOM 50%.

### STAGE 2: PARTNERSHIP FORMATION STAGE

In a second stage, you will be asked to form a partnership with a person from the other group than your own (addition or multiplication). The joint earnings will depend on the performance of both partners in the first stage.

More precisely, the joint earnings will depend on whether:

- Both are in the TOP 50%
- One is in the TOP 50% and the other is in the BOTTOM 50%
- Both are in the BOTTOM 50%

We will give you a choice between forming a partnership with a person from the TOP 50% or with a person from the BOTTOM 50% from the other group. Each partnership will be associated with a given division of earnings, which will be clearly indicated.

We will present you with 6 scenarios. Each scenario corresponds to [different joint earnings](#) and [different ways of dividing these earnings](#) between you and your partner. All the participants in the session will receive the same scenarios (and these will be numbered 1, 2, 3, 4, 5 and 6). You will have more than enough time (10 minutes in total) to study each of these scenarios carefully.

Please report your preferred choice in each scenario. You will simply need to tick one of the boxes at the bottom of the answer sheet.

After we have collected your answers for all 6 scenarios,

- One of these 6 scenarios will be selected at random
- One of the groups (Addition / Multiplication) will be selected at random and the partnerships and earnings divisions will be implemented according to the preferred choices of the selected group.

Note that the first line of the answer sheet will inform you privately about whether your performance was in the TOP 50% or BOTTOM 50% of your own group.

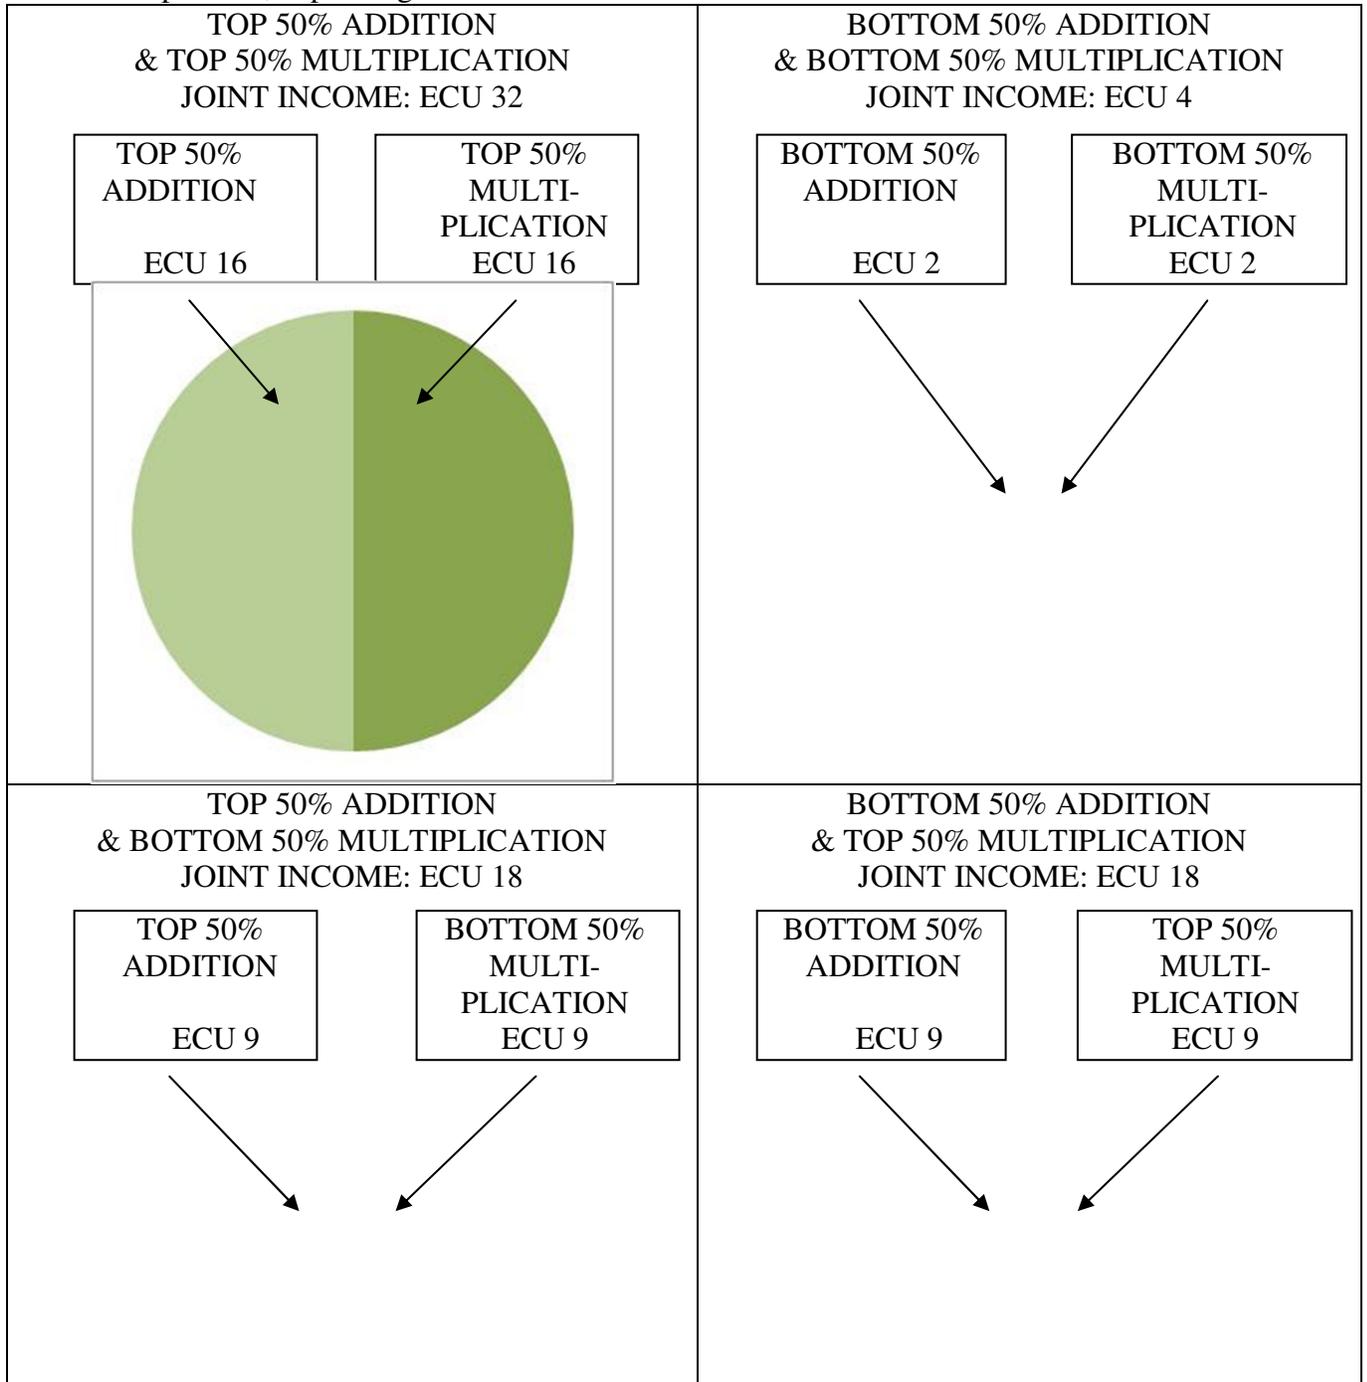

Finally, note that earnings will be indicated in experimental currency units (ECU). The exchange rate is £1 = ECU 1.5

We show you on the next page an [example](#) of answer sheet.

You are part of the **MULTIPLICATION** group.  
 Your performance in the first round was in the **TOP 50%**

If your group is chosen to lead the partnership selection, your income will depend on whom you form a partnership with in the Addition group. We indicate below how the earnings will be distributed between the partners, depending on who is matched with whom.

**INDICATE (WITH A TICK) WITH WHOM YOU WOULD PREFER TO FORM A PARTNERSHIP:**

- A person from the TOP 50% of the “Multiplication Group”
- A person from the BOTTOM 50% of the “Multiplication Group”

We will implement these preferred choices insofar as possible. If there is a shortage of partners of a given type (either "Top 50%" or "Bottom 50%"), the most demanded partners will be allocated between those who demand them in a random manner. For example, suppose "Addition" is randomly selected for the partner selection. We will randomly choose a first person in the Addition group and implement her/his choice and match him/her to a random person from her preferred type (top 50%/bottom 50%). We repeat this for each person in the Addition group one by one. If we cannot accommodate the choice because the demanded type is not available anymore, we will match the person with the other type.

At the very end, we will circulate a questionnaire that has no implications for your earnings. We would be grateful if you can fill it in carefully.
