# RISK-ADJUSTED CAPITAL ALLOCATION AND MISALLOCATION

## Abstract

We develop a theory linking “misallocation,” i.e., dispersion in static marginal products of capital (MPK), to systematic investment risks. In our setup, firms differ in their exposure to these risks, which we show leads naturally to heterogeneity in firm-level risk premia and, more importantly, MPK. The theory predicts that cross-sectional dispersion in MPK (i) depends on cross-sectional dispersion in risk exposures and (ii) fluctuates with the price of risk, and thus is countercyclical. We document strong empirical support for these predictions. We devise a strategy to quantify variation in firm-level risk exposures using data on the dispersion of expected stock market returns. Our estimates imply that risk considerations explain almost 40% of observed MPK dispersion among US firms and in particular, can rationalize a large persistent component in firm-level MPK deviations. Our framework provides a sharp link between aggregate volatility, cross-sectional asset pricing and long-run economic performance – MPK dispersion induced by risk premium effects, although not *prima facie* inefficient, lowers the average level of aggregate TFP by as much as 7%, suggesting large “productivity costs” of business cycles.

# 1 Introduction

A large and growing body of work has documented the “misallocation” of resources across firms, i.e., dispersion in the marginal product of inputs into production, and the resulting adverse effects on aggregate outcomes, such as productivity and output. Recent studies have found that even after accounting for a host of leading candidates – for example, adjustment costs, financial frictions or imperfect information – a substantial portion of observed misallocation seems to stem from other firm-specific factors, specifically, of a type that are orthogonal to firm fundamentals and are extremely persistent (if not permanent) to the firm.<sup>1</sup> Identifying exactly what – if any – underlying economic forces lead to this type of distortion has proven puzzling.

In this paper, we propose, empirically test and quantitatively evaluate just such a theory, linking capital misallocation to systematic investment risks. To the best of our knowledge, we are the first to make the connection between standard notions of the risk-return tradeoff and the resulting dispersion in the marginal product of capital (MPK) across firms. Indeed, our framework provides a natural way to translate the findings of the rich literature on cross-sectional asset pricing into the implications for the allocation of capital across firms. Further, we are able to quantify the effects of risk considerations – e.g., dispersion in risk premia across firms and the extent of aggregate volatility (and so aggregate risk) – on long-run macroeconomic outcomes, such as aggregate total factor productivity (TFP). Through the marginal product dispersion they induce, risk premium effects – although not *prima facie* inefficient – depress the average level of achieved TFP in the economy, leading to a previously unexplored “productivity cost” of business cycles, in the spirit of Lucas (1987).<sup>2</sup>

Our point of departure is a standard neoclassical model of firm investment in the face of both aggregate and idiosyncratic uncertainty. Firms discount future payoffs using a stochastic discount factor that is also a function of aggregate conditions. Critically, this setup implies that firms optimally equalize not necessarily MPK, but *expected, appropriately discounted*, MPK.<sup>3</sup> With little more structure than this, the framework gives rise to an asset pricing equation governing the firm’s expected MPK – firms with higher exposure to the aggregate risk factors require a higher risk premium on investments, which translates into a higher expected MPK. In fact, the model implies a beta pricing equation of exactly the same form that is often used to price the cross-section of stock market returns. The equation simply states that a firm’s expected MPK should be linked to the exposure of its MPK to systematic risk (i.e., the firm’s

---

<sup>1</sup>See, e.g., David and Venkateswaran (2017). We discuss the literature in more detail below.

<sup>2</sup>Our analysis is also reminiscent of the approach in Alvarez and Jermann (2004), who use data on asset prices to measure the welfare costs of aggregate fluctuations.

<sup>3</sup>Importantly, this is a statement only about expected MPK; realized MPK may differ across firms for additional reasons, i.e., uncertainty over future shocks.

“beta”), and the “price” of that risk. This firm-specific risk premium appears exactly as what would otherwise be labeled a persistent distortion or “wedge” in the firm’s investment decision.

The simple logic of the pricing equation contains substantial empirical content. Specifically, we state and empirically investigate four key predictions – (i) exposure to standard risk factors priced in asset markets is an important determinant of expected MPK, (ii) movements in factor risk prices are linked to fluctuations in conditional expected MPK, (iii) MPK dispersion is positively related to beta dispersion and (iv) movements in factor risk prices are linked to fluctuations in MPK dispersion. We use a combination of firm-level production and stock market data to provide empirical support for these predictions. For example, (i) high MPK firms tend to offer high expected stock returns, suggesting that MPK is linked to exposure to systematic risk, and further, direct measures of these exposures are positively related to levels of MPK, (ii) common return predictors such as credit spreads and the aggregate price/dividend ratio predict fluctuations in mean firm-level MPK, (iii) in the cross-section, industries with higher dispersion in factor exposures, i.e., betas, have higher dispersion in MPK and (iv) both MPK dispersion and the return on a portfolio of high-minus-low MPK stocks contain predictable, and in fact countercyclical, components, as indicated by the same return predictors as in (ii).

After establishing these empirical results, we interpret them and gauge their magnitudes through the lens of a quantitative model. To that end, we enrich our theory by explicitly linking the sources of uncertainty to idiosyncratic and aggregate productivity risk.<sup>4</sup> We add two key elements to this framework – first, a stochastic discount factor designed to match standard asset pricing facts, as has become standard in the cross-sectional asset pricing literature (e.g., Zhang (2005) and Gomes and Schmid (2010)). Second, we allow for *ex-ante* cross-sectional heterogeneity in exposure, i.e., beta, with respect to the systematic productivity risk. In other words, the productivity of high beta firms is highly sensitive to the realization of aggregate productivity, low beta firms have low sensitivity, and indeed, the productivity of firms with negative beta may move countercyclically. The investment side of the model is analytically tractable and yields sharp characterizations of firm investment decisions and MPK.

This setup is consistent with the key empirical results described above, namely, firm-level expected MPKs are dependent on exposures to the aggregate productivity shock (the systemic risk factor in the economy) and due to the countercyclical nature of factor risk prices, are countercyclical, as is the cross-sectional dispersion in expected MPK. Further, we derive an expression for aggregate TFP, which is a strictly decreasing function of MPK dispersion. By inducing MPK dispersion, cross-sectional variation in factor risk exposures and a higher price of risk (which depends on the degree of aggregate volatility) reduce the average (long-run) level

---

<sup>4</sup>These can also be interpreted as shocks to demand. Later, we show that the environment can be extended to incorporate multiple risk factors and financial shocks.

of achieved TFP. Thus, the model provides a novel, quantifiable link between financial market conditions, i.e., the nature of aggregate risk, and longer-run economic performance.

The strength of these connections rely on three key parameters – the degree of heterogeneity in firm-level risk exposures and the magnitude and time-series variation in the price of risk. We devise an empirical strategy to identify these parameters using salient moments from firm-level and aggregate stock market data, specifically, (i) the cross-sectional dispersion in expected stock returns, (ii) the market equity premium and (iii) the market Sharpe ratio. We use a linearized version of our model to derive analytical expressions for these moments and show that they are tightly linked to the structural parameters. The latter two pin down the level and volatility of the price of risk and the first identifies the cross-sectional dispersion in firm-level risk exposures. Indeed, in some simple cases of our model, the dispersion in expected MPK coming from risk premium effects is directly proportional to the dispersion in expected stock returns – intuitively, both of these moments are determined by cross-sectional variation in betas.

Before quantitatively evaluating this mechanism, we add other investment frictions to the environment, specifically, capital adjustment costs. Although they do not change the main insights from our simpler model, we uncover an important interaction between these costs and risk premia – namely, adjustment costs actually amplify the effects of beta variation on MPK dispersion. Intuitively, beta dispersion leads to persistent differences in firm-level capital choices, even if these firms have the same average level of productivity. Adjustment costs further increase the dispersion in capital, which leads to even larger effects on MPK. On their own, adjustment costs do not lead to any persistent dispersion in firm-level MPK, but they augment the effects of other factors that do, such as the variation in risk premia we analyze here.

We apply our methodology to data on US firms from Compustat/CRSP and macro/financial aggregates, e.g., productivity and stock market returns. Our estimates reveal substantial variation in firm-level betas and a sizable price of risk – together, these imply a significant amount of risk-induced MPK dispersion. For example, our results suggest risk premium effects can explain as much as 38% of total observed MPK dispersion. Importantly, this dispersion is largely persistent – in other words, risk effects lead to persistent MPK deviations at the firm level, exactly of the type that compose a large portion of observed misallocation. Indeed, they can account for as much as 47% of this permanent component in the data. The implications of these findings for the long-run level of aggregate TFP are significant – cross-sectional variation in risk reduces TFP by as much as 7%. Note that this represents a quantitative estimate of the impact of the rich findings of the cross-sectional asset pricing literature on macroeconomic performance and further, a new connection between the nature of business cycle volatility and long-run outcomes in the spirit of Lucas (1987). Here, higher aggregate volatility leads to greater aggregate risk, increasing dispersion in required rates of return and MPK and thus reducing TFP. Our results

suggest these “productivity costs” of business cycles may be substantial.

Our estimates also imply a significant countercyclical element in expected MPK dispersion. For example, our parameterized model produces a correlation between the cross-sectional variance in expected MPK and the state of the business cycle (measured by the aggregate productivity shock) of -0.31. To put this number in context, the correlation between MPK dispersion and aggregate productivity in the data is about -0.27. This result provides a risk-based explanation for the puzzling observation, made forcefully by Eisfeldt and Rampini (2006), that capital reallocation is procyclical, despite the apparently countercyclical gains – due to the countercyclical nature of factor risk prices and high beta of high MPK firms, such reallocation in downturns would require capital to flow to the riskiest of firms in the riskiest of times.

Before concluding, we perform three important additional exercises. First, we add a flexible class of firm-specific “distortions” of the type that have been emphasized in the misallocation literature. These distortions can be correlated or uncorrelated with the idiosyncratic component of firm-productivity and can be fixed or time-varying. To a first-order approximation, we show these additional factors do not affect our results or identification approach. In other words, although observed misallocation may stem from a variety of sources, our empirical strategy to measuring risk premium effects yields an accurate estimate of the contribution of this one source alone.<sup>5</sup> Second, we demonstrate the crucial role of *ex-ante* dispersion in risk exposures in generating a quantitatively realistic dispersion in expected returns. To do so, we examine a model with no beta dispersion, but adjustment costs and heterogeneity in other firm-level parameters, for example, curvature of the production function. We find that adjustment costs alone do not lead to significant expected return dispersion. Further, although heterogeneity in firm-level production parameters can generate non-negligible expected return dispersion, it is still only a relatively small fraction of the wide dispersion observed in the data, suggesting that variation in betas is a key ingredient in matching this moment. Third, we provide further, direct evidence on the extent of beta dispersion. Rather than relying on stock market data, we compute firm-level betas using production-side data by estimating time-series regressions of measures of firm-level productivity on measures of aggregate productivity. The beta is the coefficient from this regression. This approach yields beta dispersion on par with the dispersion implied by the cross-section of stock market returns.

**Related Literature.** Our paper relates to several branches of the literature. First is the large body of work investigating and quantifying the effects of resource misallocation across firms, seminal examples of which include Hsieh and Klenow (2009) and Restuccia and Rogerson

---

<sup>5</sup>We also analyze distortions that can be correlated with the aggregate shock and show that under plausible assumptions, our approach yields a conservative estimate of risk premium effects.

(2008). A number of papers have explored the role of particular economic forces in leading to misallocation. For example, Asker et al. (2014) study the role of capital adjustment costs, Midrigan and Xu (2014), Moll (2014) and Buera et al. (2011) financial frictions, Peters (2016) markup dispersion and David et al. (2016) information frictions.<sup>6</sup> Gopinath et al. (2017) and Kehrig and Vincent (2017) show that the interactions of adjustment costs and financial frictions are important in determining the recent dynamics of misallocation in Spain and the extent of misallocation across plants within firms, respectively. David and Venkateswaran (2017) provide an empirical methodology to disentangle various sources of capital misallocation and establish a large role for other firm-specific factors, in particular, ones that are essentially permanent to the firm. We build on this literature by exploring the implications of a different dimension of financial markets for marginal product dispersion, namely, the risk-return tradeoff faced by risk-averse investors. Importantly, our theory generates what appears to be a permanent firm-specific “wedge” exactly of the type found by David and Venkateswaran (2017), but which in our framework is a function of each firm’s exposure to aggregate risk. The addition of aggregate risk is a key innovation of our analysis – existing work has typically abstracted from this channel.<sup>7</sup> We show that the link between aggregate risk and observed misallocation is quite tight in the presence of heterogeneous exposures to that risk.

Kehrig (2015) documents in detail the countercyclical nature of productivity dispersion. We build on this finding by relating fluctuations in MPK dispersion to time-series variation in the price of risk. A growing literature, starting with Eisfeldt and Rampini (2006), investigates the reasons underlying the observation that capital reallocation is procyclical. This indeed seems puzzling since, given higher cross-sectional dispersion in MPK in downturns, one should expect to see capital flowing to highly productive, high MPK firms in recessions. Our results bear on that observation by noting that the countercyclical nature of factor risk prices, in conjunction with heterogeneity in firm-level risk exposures, go some way toward reconciling this puzzle.

Our work exploits the insight, due to Cochrane (1991) and Restoy and Rockinger (1994), that stock returns and investment returns are closely linked. Indeed, under the assumption of constant returns to scale, stock and investment returns effectively coincide. Crucially, for our purposes, investment returns are intimately linked with the marginal product of capital. Balvers et al. (2015) explore and confirm the relationship under deviations from constant returns to scale. In this context, our work is closely related to the growing literature that examines the

---

<sup>6</sup>Many papers study the role of firm-specific distortions, e.g., Bartelsman et al. (2013). Restuccia and Rogerson (2017), Hopenhayn (2014) and Eisfeldt and Shi (2018) provide excellent overviews of recent work on capital misallocation/reallocation.

<sup>7</sup>Two important exceptions are Gopinath et al. (2017), who analyze the transitional effects of an interest rate shock on misallocation, and Kehrig (2015), who constructs a model of misallocation over the business cycle featuring overhead inputs. Neither of these papers examines risk premium effects, either because there is no aggregate uncertainty or firms are risk-neutral.

cross-section of stock returns by viewing them from the perspective of investment returns, e.g., Zhang (2005), Gomes et al. (2006) and Liu et al. (2009), and forcefully summarized in Zhang (2017). This literature interprets common risk factors such as the Fama and French (1992) factors through firms’ investment policies and shows that investment-based factors are priced in the cross-section of returns. Our objective is quite different and in some sense turns that logic on its head, in that we examine investment returns and the marginal product of capital as a manifestation of exposure to systematic risk, most readily measured through stock returns. Relatedly, Binsbergen and Opp (2017) also investigate the implications of asset market considerations for the real economic decisions of firms. They propose a framework where distortions in agents’ subjective beliefs lead to “alphas,” i.e., cross-sectional mispricings, and real efficiency losses, whereas we focus on the marginal product dispersion induced by heterogeneity in aggregate risk exposures. Our empirical work establishes a connection between observed marginal products and asset market outcomes and our quantitative work uses a workhorse macroeconomic model of firm dynamics augmented to feature risk-sensitive agents and aggregate risk to evaluate the implications of this insight. One of our key messages shares a common theme with this line of work – financial market considerations can have sizable effects on real outcomes by affecting capital allocation decisions.<sup>8</sup>

## 2 Motivation

In this section, we lay out a simple version of the standard, frictionless neoclassical theory of investment to motivate our empirical explorations. Section 4 enriches this environment for purposes of our quantitative work.

Firms produce output using capital and labor according to a standard Cobb-Douglas production function. Labor is chosen period-by-period in a spot market at a competitive wage. At the end of each period, firms choose investment in new capital, which becomes available for production in the following period so that  $K_{it+1} = I_{it} + (1 - \delta) K_{it}$ , where  $\delta$  is the rate of depreciation. Let  $\Pi_{it} = \Pi_{it}(X_t, Z_{it}, K_{it})$  denote the operating profits of the firm – revenues net of labor costs – where  $X_t$  and  $Z_{it}$  denote aggregate and idiosyncratic shocks to firm profitability, respectively, and  $K_{it}$  the firm’s level of capital. The analysis can accommodate a number of interpretations of the fundamental shocks, for example, as productivity or demand shifters. Given the Cobb-Douglas technology, the profit function takes a Cobb-Douglas form, is homogeneous in  $K$  of degree  $\theta \leq 1$  and is proportional to revenues.<sup>9</sup> The marginal product of capital

---

<sup>8</sup>Relatedly, David et al. (2014) find that risk considerations play an important role in determining the allocation of capital across countries, i.e., can explain some portion of the “Lucas Paradox.”

<sup>9</sup>This structure arises, for example, if firms are perfectly competitive and the production function features decreasing returns to scale or firms are monopolistically competitive and face CES demand curves.

is equal to  $MPK_{it} = \theta \frac{\Pi_{it}}{K_{it}}$ . The payout of the firm in period  $t$  is equal to  $D_{it} = \Pi_{it} - I_{it}$ .

Firms discount future cash flows using a stochastic discount factor (SDF),  $M_{t+1}$ , which may be correlated with the aggregate component of firm fundamentals, i.e., with  $X_t$ . We can write the firm's problem in recursive form as

$$V(X_t, Z_{it}, K_{it}) = \max_{K_{it+1}} \Pi_{it}(X_t, Z_{it}, K_{it}) - K_{it+1} + (1 - \delta) K_{it} + \mathbb{E}_t [M_{t+1} V(X_{t+1}, Z_{it+1}, K_{it+1})] , \quad (1)$$

where  $\mathbb{E}_t[\cdot]$  denotes the firm's expectations conditional on time  $t$  information. Standard techniques give the Euler equation

$$1 = \mathbb{E}_t [M_{t+1} (MPK_{it+1} + 1 - \delta)] \quad \forall i, t . \quad (2)$$

**MPK dispersion.** An immediate consequence of expression (2) is that MPK (or even expected MPK) need not be equated across firms; rather, it is only appropriately discounted expected MPK that is equalized. To the extent that firms load differently on the SDF, their expected MPK will differ. Assuming a single source of aggregate risk for the sake of illustration, Appendix B.1 derives the following factor model for expected MPK:<sup>10</sup>

$$\mathbb{E}_t [MPK_{it+1}] = \alpha_t + \beta_{it} \lambda_t . \quad (3)$$

Here,  $\alpha_t = r_{ft} + \delta$  is the "risk-free" MPK (the user cost of capital), where  $r_{ft}$  is the risk-free interest rate,  $\beta_{it} \equiv -\frac{\text{cov}_t(M_{t+1}, MPK_{it+1})}{\text{var}_t(M_{t+1})}$  captures the exposure, or loading, of the firm's MPK on the SDF, i.e., the riskiness of the firm, and  $\lambda_t \equiv \frac{\text{var}_t(M_{t+1})}{\mathbb{E}_t[M_{t+1}]}$  is the market price of that risk. In the language of asset pricing, the Euler equation gives rise to a conditional one-factor model for expected MPK. Expression (3) highlights that expected MPK is not necessarily common across firms and is a function of the risk-free rate of return, the firm's beta on the SDF, which may vary across firms, and the market price of risk. The cross-sectional variance of date  $t$  conditional expected MPK is then equal to

$$\sigma_{\mathbb{E}_t[MPK_{it+1}]}^2 = \sigma_{\beta_t}^2 \lambda_t^2 , \quad (4)$$

where  $\sigma_{\beta_t}^2$  is the cross-sectional variance of conditional betas. The extent to which risk considerations lead to dispersion in expected MPK depends on (i) the cross-sectional variation in firm-level risk exposures, i.e., beta and (ii) the price of risk. Further, given persistence in

---

<sup>10</sup>It is straightforward to generalize the results to environments featuring multiple aggregate risk factors, such as the Fama and French (1992) 3-factor model or the Q-factor model of Hou et al. (2015) and Zhang (2017). We provide a multi-factor extension of our baseline theory in Section 6.1.

firm-level betas, the theory can clearly generate persistent differences in firm-level MPK, which are driven by the dispersion in required rates of return across firms.<sup>11</sup>

The strength of the mechanism linking dispersion in MPK to exposure to aggregate risk can be understood by inspection of expression (4) – predicted MPK dispersion is increasing in the dispersion in betas and also in the price of risk,  $\lambda$ . A key observation underlying our analysis is that asset pricing data suggest that risk prices are rather high. For example, a lower bound is given by the Sharpe ratio on the market portfolio, estimated to be around 0.5. However, even easily implementable trading strategies such as those based on value-growth portfolios, or momentum, suggest numbers closer to 0.8, while hedge fund strategies report Sharpe ratios in excess of one. Taken at face value, these numbers suggest the possibility for substantial MPK dispersion – even in otherwise frictionless environments – after taking risk exposure in account.

**Empirical Predictions.** Even under the simple structure we have outlined thus far, the theory has a good deal of empirical content. Specifically, the expressions laid out above contain a number of both cross-sectional and time-series predictions:

1. *Exposure to standard risk factors is a determinant of expected MPK.* Expression (3) shows that the same factors that determine the cross-section of asset returns – namely, exposure to the SDF – determine the cross-section of MPK. Firms with a higher loading on the SDF, i.e., higher beta, should have higher conditional expected MPK.

2. *Variation in the price of risk,  $\lambda_t$ , leads to predictable variation in mean expected MPK.* In particular, the mean conditional expected MPK should increase with the price of risk. This is the time-series implication of expression (3) – holding fixed the distribution of beta, movements in  $\lambda_t$  should positively affect the mean expected MPK. Since the price of risk is known to be countercyclical, this adds a countercyclical element to the mean conditional expected MPK.

3. *MPK dispersion is related to beta dispersion.* Expression (4) shows that variation in the cross-section of MPK is proportional to the variation in beta. Segments of the economy, for example, industries, with higher dispersion in beta should display higher dispersion in MPK.

---

<sup>11</sup>To see this more clearly, we can take the unconditional expectation of equation (3) to obtain an approximate expression for the variance of mean MPK as  $\sigma_{\mathbb{E}[MPK]}^2 \approx \sigma_{\beta}^2 \lambda^2$ , where  $\sigma_{\beta}^2 \equiv \sigma_{\mathbb{E}[\beta_{it}]}^2$  denotes the variance of unconditional betas and  $\lambda \equiv \mathbb{E}[\lambda_t]$  the unconditional expectation of the price of risk. The approximation is valid as long as  $\text{cov}(\beta_i, \text{cov}(\beta_{it}, \lambda_t))$  is small. In line with the results in Lewellen and Nagel (2006), we find the time-series variation in betas to be quite modest. In the case of constant betas, for example (which we assume in our quantitative model), or if time variation in beta is orthogonal to variation in  $\lambda$ , the expression is exact.

4. *MPK dispersion is positively correlated with the price of risk.* Expression (4) links MPK dispersion to time-series variation in the price of risk. Given the dispersion in beta, when required compensation for bearing risk increases, MPK dispersion should increase as well.

**Illustrative examples.** Section 3 investigates each of these predictions in detail. Before doing so, however, it is useful to consider a number of more concrete illustrative examples (derivations for this section are in Appendix B).

*Example 1: no aggregate risk (or risk neutrality).* In the case of no aggregate risk, we have  $\beta_{it} = 0 \forall i, t$ , i.e., all shocks are idiosyncratic to the firm. Expressions (3) and (4) show that there will be no dispersion in expected MPK and for each firm,  $\mathbb{E}_t [MPK_{it+1}] = r_f + \delta$ , which is simply the riskless user cost of capital (which is constant in the absence of aggregate shocks). This is the standard result from the stationary models widely used in the misallocation literature where, without additional frictions, expected MPK should be equalized across firms.<sup>12</sup> This expression also holds in an environment with aggregate shocks but risk neutral preferences, which implies  $M_{t+1}$  is simply a constant (equal to the time discount factor).

*Example 2: CAPM.* In the CAPM, the SDF is linearly related to the market return, i.e.,  $M_{t+1} = a - bR_{mt+1}$  for some constants  $a$  and  $b$ . Because the market portfolio is itself an asset with  $\beta = 1$ , it is straightforward to derive

$$\mathbb{E}_t [MPK_{it+1}] = \alpha_t + \underbrace{\frac{\text{cov}_t(R_{mt+1}, MPK_{it+1})}{\text{var}_t(R_{mt+1})}}_{\beta_{it}} \underbrace{\mathbb{E}_t [R_{mt+1} - R_{ft}]}_{\lambda_t},$$

i.e., expected MPK is determined by the covariance of the firm's MPK with the market return, which is the the risk factor in this environment. The price of risk is equal to the expected excess return on the market portfolio, i.e., the equity premium ( $R_{ft}$  is the risk-free rate of return from period  $t$  to  $t + 1$ ).

*Example 3: CCAPM.* In the case that the utility function is CRRA with coefficient of relative risk aversion  $\gamma$ , standard approximation techniques give the pricing equation from the

---

<sup>12</sup>With time-to build for capital and uncertainty over upcoming shocks there may still be dispersion in *realized* MPK, but not in *expected* terms, and so these forces do not lead to persistent firm-level MPK deviations.

consumption capital asset pricing model:

$$\mathbb{E}_t [MPK_{it+1}] = \alpha_t + \underbrace{\frac{\text{cov}_t(\Delta c_{t+1}, MPK_{it+1})}{\text{var}_t(\Delta c_{t+1})}}_{\beta_{it}} \underbrace{\gamma \text{var}_t(\Delta c_{t+1})}_{\lambda_t},$$

where  $\Delta c_{t+1}$  denotes log consumption growth. Expected MPK is determined by the covariance of the firm’s MPK with consumption growth. The price of risk is the product of the coefficient of relative risk aversion and the conditional volatility of consumption growth.

### 3 Empirical Results

In this section, we investigate the empirical predictions outlined in Section 2.

**Data.** Our data come primarily from the Center for Research in Security Prices (CRSP) and Compustat. We use data on nonfinancial firms with common equities listed on the NYSE, NASDAQ, or AMEX over the period 1965 to 2015. We supplement this panel with time-series data on market factors and aggregate conditions related to the price of risk. We use data on the Fama and French (1992) (Fama-French) factors, aggregate dividends and stock market values from Shiller (2005) and two measures of credit spreads: the Gilchrist and Zakrajsek (2012) (GZ) credit spread and the excess bond premium.<sup>13</sup> We measure firm capital stock,  $K_{it}$ , as the (net of depreciation) value of property, plant and equipment (Compustat series PPENT) and firm revenue,  $Y_{it}$ , as reported sales (series SALE).<sup>14</sup> Ignoring constant terms, which will play no role in our analysis, we measure the marginal product of capital (in logs, henceforth denoted with lowercase) as  $mpk_{it} = y_{it} - k_{it}$ .<sup>15</sup> Appendix A provides further details on how we construct our dataset and the series that we use. We can now revisit the predictions from Section 2.

1. *Exposure to standard risk factors is a determinant of expected MPK.* We investigate this key implication of our framework in several ways.

**Portfolio sorts.** First, we examine the relationship between MPK and stock market returns. To do so, we form MPK-sorted portfolios of firms. This approach follows widespread practice in empirical finance, which has generally moved from addressing variation in individual firm

---

<sup>13</sup>Data on the Fama-French factors are from Kenneth French’s website, <http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/>. We obtain updated data on the price/dividend ratio from Robert J. Shiller’s website, <http://www.econ.yale.edu/~shiller/> and updated measures of the GZ spread and excess bond premium from Simon Gilchrist’s website, <http://people.bu.edu/sgilchri/>.

<sup>14</sup>Using book assets, a broader notion of firm capital, yields similar results.

<sup>15</sup>In our setup, operating profits are proportional to revenues, making this a valid measure of the  $mpk$ .

returns to returns on portfolios of firms, sorted by factors that are known to predict returns. In our setting, this procedure proves useful to eliminate firm-specific factors unrelated to MPK that may affect returns and so allows us to hone in on the predictability of excess returns by MPK.<sup>16</sup> We sort firms into five portfolios based on their year  $t$  MPK, where portfolio 1 contains low MPK firms and portfolio 5 high MPK ones. The portfolios are rebalanced annually. We then compute the contemporaneous and one-period ahead equal-weighted excess stock return to each portfolio, denoted  $r_t^e$  and  $r_{t+1}^e$ , respectively.<sup>17</sup> We also compute the excess return on a high-minus-low MPK portfolio (MPK-HML), which is an annually rebalanced portfolio that is long on stocks in the highest MPK portfolio and short on stocks in the lowest.

We report the results in Panel A of Table 1. The table reveals a strong relationship between MPK and stock returns – high MPK portfolios tend to earn high excess returns. The first row shows that the difference in contemporaneous returns between high and low MPK firms, i.e., the excess return on the MPK-HML portfolio, is over 8% annually. The second row confirms that this finding does not simply result from the simultaneous response of stock returns and MPK to the realization of unexpected shocks – one-period ahead excess returns are in fact predictable by MPK. Indeed, the predictable spread on the MPK-HML portfolio is almost 5% annually. Both the contemporaneous and future MPK-HML spreads are statistically different from zero at the 99% level. Thus, high MPK tend to offer high stock returns, both in a realized and an expected sense, suggesting that MPK differences reflect exposure to risk factors for which investors demand compensation in the form of a higher rate of return.

The focus in the misallocation literature is generally on within-industry variation in MPK.<sup>18</sup> We therefore also perform industry-adjusted portfolio sorts and find that the relationship between MPK and stock returns is also present within individual industries. To control for industry effects, we demean firm-level  $mpk$  by subtracting the mean  $mpk$  within each industry-year, and sort firms based on this de-measured measure.<sup>19</sup> Panel B of Table 1 reports the within-industry results. The relationship between MPK and stock returns remains strong even when comparing across firms within a particular industry, both in an economic and statistical sense – the MPK-HML contemporaneous excess return remains over 8% annually and the future excess return is over 2.5%. Both are statistically significant at the 99% level.

In Appendix D, we explore a number of variants of Table 1. For example, we expand the

---

<sup>16</sup>The portfolio approach can also help reduce the effects of potential measurement error, for example, in firm-level capital stocks.

<sup>17</sup>When computing future returns, we follow Fama and French (1992) and associate the MPK for fiscal year  $t$  with returns from July of year  $t + 1$  to June of year  $t + 2$ .

<sup>18</sup>There may be heterogeneity across industries on a number of dimensions, for example, in production function coefficients or industry-level exposure to aggregate shocks.

<sup>19</sup>This is equivalent to extracting industry-year fixed-effects. We define industries at the 4-digit SIC code level and examine industry-year pairs with at least 10 observations.

Table 1: Excess Returns on MPK-Sorted Portfolios

<i>Portfolio</i>	Low	2	3	4	High	MPK-HML
Panel A: Not Industry-Adjusted						
$r_t^e$	7.00** (2.01)	9.08** (2.53)	10.67*** (2.93)	12.00*** (3.09)	15.25*** (3.71)	8.25*** (4.54)
$r_{t+1}^e$	8.60** (2.48)	12.27*** (3.47)	13.48*** (3.80)	13.73*** (3.62)	13.48*** (3.36)	4.87*** (2.81)
Panel B: Industry-Adjusted						
$r_t^e$	6.98 (1.63)	8.91** (2.52)	10.59*** (3.05)	12.28*** (3.30)	15.78*** (3.73)	8.80*** (9.54)
$r_{t+1}^e$	11.10*** (2.61)	11.55*** (3.35)	12.71*** (3.75)	12.70*** (3.50)	13.69*** (3.36)	2.59*** (2.98)

*Notes:* This table reports stock market returns for portfolios sorted by *mpk*.  $r_t^e$  denotes equal-weighted contemporaneous annualized monthly excess stock returns (over the risk-free rate) measured in the year of the portfolio formation from January to December of year  $t$ .  $r_{t+1}^e$  denotes the analogous future returns, measured from July of year  $t + 1$  to June of year  $t + 2$ . Industry adjustment is done by de-meaning *mpk* by industry-year and sorting portfolios on de-meaned *mpk*, where industries are defined at the 4-digit SIC code level.  $t$ -statistics in parentheses, computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

number of portfolios, examine measures of unlevered returns and consider longer-horizon future returns. The relationship between MPK and stock returns continues to hold under all these alternatives. We perform double-sorts on size and book-to-market and verify that the return spreads based on MPK are not fully explained by the latter two factors (although they are both correlated with MPK). We also present summary statistics of the portfolios across a number of characteristics and consider several additional measurement issues (for example, we show that the results are unlikely to be driven by unmeasured intangible capital).

**Measures of risk exposures and expected MPK.** The second way we verify prediction 1 is to directly relate firm MPK to measures of risk exposures. To do so, we estimate regressions of the form

$$mpk_{it+1} = \psi_0 + \psi_\beta \beta_{it} + \zeta_{it+1}, \quad (5)$$

where  $\beta_{it}$  is a measure of firm  $i$  exposure to aggregate risk at time  $t$ . The specification tests whether observable measures of firm-level risk exposures are indeed correlated with higher MPK. We estimate (5) at an annual frequency and lag the right-hand side variable to control for the simultaneous effect of unexpected shocks on contemporaneous measures of beta and MPK. We construct four different measures of these exposures. First, we compute standard CAPM and Fama-French stock market betas ( $\beta_{CAPM}$  and  $\beta_{FF}$ , respectively) by estimating firm-level regressions of stock returns on the risk factors from each of these models. In the

CAPM, the single risk factor is the aggregate market return. The three Fama-French factors are the market return, the return on a portfolio that is long in small firms and short in large ones (SMB), which captures the size premium and the return on a portfolio that is long in high book-to-market firms and short in low ones (HML), which captures the value premium. In each model, the coefficient on the risk factor(s) yields a measure of beta. To obtain a single measure of risk exposure in the multi-factor Fama-French model, we combine the estimated betas into a single value using estimated prices of risk from Fama and MacBeth (1973) regressions. We provide details of these calculations in Appendix A.

With these measures in hand, we are in a position to estimate equation (5). We report the results in columns (1)-(2) in Table 2. Both measures have significant explanatory power for subsequent MPK. For example, the estimate in column (1) implies that each unit increase in the CAPM beta is associated with a 20% increase in expected MPK.

Table 2: Predictive Regressions of MPK on Aggregate Risk Exposures

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
$\beta_{CAPM}$	0.209*** (51.53)				0.014*** (3.48)			
$\beta_{FF}$		0.068*** (63.14)				0.005*** (4.91)		
$\beta_{CAPM,MPK}$			0.065*** (13.77)				0.024*** (4.31)	
$\beta_{FF,MPK}$				4.005*** (25.00)				1.097*** (6.16)
Observations	108571	107845	81559	81062	103488	102820	76832	76351
$R^2$	0.024	0.036	0.002	0.008	0.059	0.059	0.065	0.065
Firms	10270	10229	8687	8655	9991	9941	8406	8380
F.E.	No	No	No	No	Yes	Yes	Yes	Yes
Controls	No	No	No	No	Yes	Yes	Yes	Yes

*Notes:* This table reports the results of a panel regression of year-ahead  $mpk$  regressed on measures of firm exposure to aggregate risk. Each observation is a firm-year. F.E. denotes the presence of industry-year fixed effects. When we include fixed-effects, we cluster standard errors by industry-year.  $t$ -statistics in parentheses. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

Both of these measures of firm-level risk exposures are based only on stock market data. Although our theory implies these should be related to MPK (and they have a rich tradition in asset pricing), expression (3) suggests that we look directly at the exposure of firm-level MPK to aggregate risk factors. To do so, we perform the same two exercises just described, but instead using firm-level MPK – namely, we regress  $mpk$  on the market return and Fama-French factors to obtain two direct measures of MPK exposure to aggregate risk ( $\beta_{CAPM,MPK}$  and  $\beta_{FF,MPK}$ )

and estimate specification (5) using these measures as the predictive variable. We report the results in columns (3) and (4) of Table 2. The table shows that, similar to stock market betas, firm-level “MPK betas” are significant predictors of future firm MPK. In sum, our findings in Table 2 confirm a key implication of expression (3): firm-level risk exposures – measured using stock market or MPK exposures – are significant determinants of firm-level expected MPK.

In columns (5)-(8) of Table 2, we estimate analogous regressions with the addition of industry-year fixed-effects and a set of standard firm-level controls, namely, market capitalization, book-to-market ratio, profitability, and market leverage.<sup>20</sup> All of the beta coefficients remain positive and statistically significant.

2. *Variation in the price of risk,  $\lambda_t$ , leads to predictable variation in mean expected MPK.* Expression (3) implies that the price of risk should positively predict the level of expected MPK. To test this implication, we estimate time-series regressions of the form:

$$\mathbb{E}[mpk_{it+1}] = \psi_0 + \psi_1 \lambda_t + \zeta_{t+1} , \quad (6)$$

where  $\mathbb{E}[mpk_{it+1}]$  denotes the average *mpk* in period  $t + 1$  and  $\lambda_t$  denotes three different proxies of the price of risk: the price/dividend ratio (PD) on the aggregate stock market and two measures of credit spreads – the Gilchrist and Zakrajsek (2012) (GZ) spread, a high-information and duration-adjusted measure of the mean credit spread and the excess bond (EB) premium, which measures the portion of the GZ spread not attributable to default risk.<sup>21</sup> These are standard proxies for risk prices that have been widely used in the literature. We estimate specification (6) using quarterly data on these measures, where the left-hand side variable is one year (four-quarter) ahead *mpk*.<sup>22</sup> Table 3 reports the results of these regressions. In line with the theory, column (1) shows that the PD ratio (likely negatively correlated with the price of risk) predicts lower future MPK, while columns (2) and (3) show that the GZ spread and the EB premium (likely positively correlated with the price of risk) predict higher future MPK. Thus, the table confirms that time-variation in risk premia forecast future levels of MPK.

3. *MPK dispersion is related to beta dispersion.* Expression (4) implies that across groups of firms or segments of the economy, dispersion in expected MPK should be positively related to

---

<sup>20</sup>We describe these series in Appendix A.

<sup>21</sup>We extract the cyclical component of the PD ratio and mean *mpk* using a one-sided Hodrick-Prescott filter. The credit spread measures do not exhibit significant longer-term trends.

<sup>22</sup>To control for the changing composition of firms, for each quarter, we include only firms that were present in the previous quarter and calculate changes in the mean *mpk* for these firms. We then use those changes to construct a composition-adjusted series for mean *mpk* which is unaffected by new additions or deletions from the dataset. We further detail this procedure in Appendix A.

Table 3: Predictability of Mean MPK

	(1)	(2)	(3)
PD Ratio	-0.341*** (-3.24)		
GZ Spread		4.457*** (3.44)	
EB Premium			7.041*** (3.20)
Observations	166	166	166
$R^2$	0.120	0.122	0.100

*Notes:* This table reports time-series regressions of four-quarter ahead average  $mpk$  on measures of the price of risk.  $t$ -statistics are in parentheses, which are computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

dispersion in risk exposures. We investigate this prediction using variation in the dispersion of firm-level betas and expected stock market returns across industries. Specifically, for each industry in each year, we compute the standard deviation of MPK,  $\sigma(mpk)$ , expected stock returns,  $\sigma(\mathbb{E}[r])$ , and beta,  $\sigma(\beta)$ . We then estimate regressions of industry-level MPK dispersion on the dispersion in expected returns and betas, i.e.,

$$\sigma(mpk_{jt+1}) = \psi_0 + \psi_1\sigma(x_{jt}) + \zeta_{jt+1} \quad x_{jt} = \mathbb{E}[r_{jt}], \beta_{jt},$$

where  $j$  denotes industry. Again, to avoid potential simultaneity biases from the realization of shocks, we lag the independent variables (dispersion in expected returns and betas).

Table 4 reports the results of these regressions and demonstrates that indeed, industries with higher dispersion in expected stock returns and beta exhibit greater dispersion in MPK. Column (1) reveals this fact using expected returns calculated from the Fama-French model.<sup>23</sup> Variation in expected return dispersion predicted by the Fama-French model explains over 20% of the variation in MPK dispersion across industry-years. Column (2) regresses MPK dispersion on dispersion in each of the three individual factors – variation in the beta on each factor is significantly related to MPK dispersion. Next, we repeat the exercise using dispersion in MPK betas (described above) as the right-hand side variables. The results in column (3) show that industries with greater dispersion in MPK betas (on each of the Fama-French factors) exhibit greater dispersion in MPK. Columns (4)-(6) add year fixed-effects and a number of controls capturing additional measures of firm heterogeneity within industries – the

<sup>23</sup>Expected returns are computed using a standard two-stage approach – first, we estimate the betas from time-series regressions as described under prediction 1. We then measure expected returns as the predicted values from cross-sectional Fama-Macbeth regressions of returns on these betas. We provide further details in Appendix A.

standard deviations of profitability, size, book-to-market, and market leverage. Across these specifications, measures of within-industry heterogeneity in expected returns and aggregate risk exposures remain positive and significant predictors of within-industry dispersion in MPK.<sup>24</sup>

Table 4: Industry-Level Dispersion in MPK, Expected Stock Returns and Beta

	(1)	(2)	(3)	(4)	(5)	(6)
$\sigma(\mathbb{E}[r])$	2.71*** (30.11)			1.20*** (9.82)		
$\sigma(\beta_{MKT})$		0.11*** (6.48)			0.08*** (3.31)	
$\sigma(\beta_{HML})$		0.14*** (11.18)			0.10*** (5.61)	
$\sigma(\beta_{SMB})$		0.14*** (13.72)			0.07*** (5.77)	
$\sigma(\beta_{CAPM,MPK})$			0.01*** (8.58)			0.09*** (4.08)
$\sigma(\beta_{HML,MPK})$			0.06*** (7.96)			0.06*** (4.80)
$\sigma(\beta_{SMB,MPK})$			0.06*** (10.38)			0.06*** (5.70)
Observations	3203	3210	2398	3188	3194	2380
$R^2$	0.221	0.265	0.200	0.261	0.285	0.348
Industries	157	161	142	153	156	138
Year F.E.	No	No	No	Yes	Yes	Yes
Controls	No	No	No	Yes	Yes	Yes

*Notes:* This table reports a panel regression of the dispersion in  $mpk$  within industries on lagged measures of dispersion in risk exposure within those industries. An observation is an industry-year.  $\mathbb{E}[r]$  is the expected return computed from the Fama-French model.  $\beta$  denotes the stock return beta on the Fama-French factors and  $\beta_{MPK}$  the  $mpk$  beta on the same factors.  $t$ -statistics are in parentheses. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

4. *MPK dispersion is positively correlated with the price of risk.* Expression (4) implies that the price of risk is positively related to MPK dispersion. We investigate this prediction in two ways. First, we show that the indicators of the price of risk considered before (PD ratio, GZ spread, and EB premium) predict time-series variation in MPK dispersion. Second, we show that the expected return on the high-minus-low MPK portfolio is also predicted by these measures.

<sup>24</sup>The results are robust to using different asset pricing models to compute betas and expected returns, such as the CAPM and Hou et al. (2015) investment-CAPM models. The relationship is robust to a variety of different controls and industry definitions as well. Finally, the results are qualitatively similar when we use the inter-quartile range instead of the standard deviation as our measure of within-industry dispersion.

To perform these tests, we estimate regressions of the form

$$y_{t+1} = \psi_0 + \psi_1 \lambda_t + \zeta_{t+1}, \quad y_{t+1} = \sigma (mpk_{t+1}), r_{HML,t+1},$$

where  $\lambda_t$  denotes the various proxies for the price of risk. Columns (1)-(3) of table 5 report regressions of the within-industry standard deviation of MPK,  $\sigma (mpk_{t+1})$ , on the lagged values of these measures. Each predicts MPK dispersion, and in the direction the theory suggests: the GZ Spread and excess bond premium predict greater MPK dispersion, while a higher PD ratio predicts lower dispersion.<sup>25</sup> Because our measures of the price of risk are countercyclical, the results imply that variation in risk premia induce a countercyclical component in MPK dispersion, in line with (and potentially in part accounting for) the well known evidence of countercyclicality documented in Eisfeldt and Rampini (2006).<sup>26</sup>

Table 5: Predictability of MPK Dispersion and MPK-HML Portfolio Return

	MPK Dispersion			MPK-HML Portfolio Returns		
	(1)	(2)	(3)	(4)	(5)	(6)
PD Ratio	-0.112*** (-3.52)			-0.013* (-1.84)		
GZ Spread		1.226*** (3.23)			0.269** (2.27)	
EB Premium			3.415*** (4.44)			0.426** (2.32)
Observations	166	166	166	166	166	166
$R^2$	0.103	0.072	0.185	0.031	0.082	0.068

*Notes:* This table reports time-series regressions of four-quarter ahead *mpk* dispersion and MPK-HML portfolio returns on measures of the price of risk. *t*-statistics are in parentheses, computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

Next, columns (4)-(6) of Table 5 report regressions using the cumulative twelve month return on the MPK-HML portfolio,  $r_{HML,t+1}$  as the dependent variable. The GZ spread and excess bond premium predict higher future returns on the MPK-HML portfolio, while the PD ratio predicts lower future returns, implying that a high price of risk predicts a greater return spread between high and low MPK firms. In sum, our findings confirm that indeed, investors require greater compensation (in the form of a higher rate of return) to invest in high MPK firms at times when risk premia are high, leading to a predictable and countercyclical increase

<sup>25</sup>We again extract the cyclical component of the PD ratio and *mpk* dispersion using a one-sided Hodrick-Prescott filter. The results are qualitatively similar when we use a measure of unconditional (not industry-adjusted) MPK dispersion as the dependent variable.

<sup>26</sup>We report the correlations of these measures with de-trended GDP and TFP in Table 9 in Appendix A.2.

in dispersion and widening of the spread between low and high MPK firms.<sup>27</sup>

## 4 Quantitative Model

In the next two sections, we use a more detailed version of the investment model laid out above to quantitatively investigate the contribution of heterogeneous risk premia to observed MPK dispersion. The model is kept deliberately simple in order to isolate the role of our basic mechanism, namely dispersion in exposure to systematic risk. The theory consists of two main building blocks: (i) a stochastic discount factor, which we directly parameterize to be consistent with salient patterns in financial markets, i.e., high and countercyclical prices of risk and (ii) a cross-section of heterogeneous firms, which make optimal investment decisions in the presence of firm-level and aggregate risk, given the stochastic discount factor. Specifying the stochastic discount factor exogenously allows us to sidetrack challenges with generating empirically relevant risk prices in general equilibrium, and focus on gauging the quantitative strength of our mechanism. To hone in on the effects of risk premia, we begin with a simplified version in which we abstract from additional adjustment frictions. In this case, our framework yields exact closed form solutions for firm investment decisions. In Section 4.3, we extend the model to include capital adjustment costs. Our theoretical results there reveal an important amplification effect of these costs on the impact of risk premia.<sup>28</sup>

### 4.1 The Environment

**Heterogeneity in risk exposures.** The setup is a fleshed-out version of that in Section 2. We consider a discrete time, infinite-horizon economy. A continuum of firms of fixed measure one, indexed by  $i$ , produce a homogeneous good using capital and labor according to:

$$Y_{it} = X_t^{\hat{\beta}_i} \hat{Z}_{it} K_{it}^{\theta_1} N_{it}^{\theta_2}, \quad \theta_1 + \theta_2 < 1.$$

Firm productivity (in logs) is equal to  $\hat{\beta}_i x_t + \hat{z}_{it}$ , where  $x_t$  denotes an aggregate component that is common across firms and  $\hat{\beta}_i$  captures the exposure of the productivity of firm  $i$  to aggregate conditions.<sup>29</sup> We assume that  $\hat{\beta}_i$  is distributed as  $\hat{\beta}_i \sim \mathcal{N}(\bar{\beta}, \sigma_{\hat{\beta}}^2)$  across firms. Heterogeneity in this exposure is a key ingredient of our framework – cross-sectional variation in  $\hat{\beta}_i$  will lead directly to dispersion in expected MPK. The term  $\hat{z}_{it}$  denotes a firm-specific,

---

<sup>27</sup>De-trended GDP also predicts countercyclical MPK dispersion and return spreads between high and low MPK firms.

<sup>28</sup>We also consider the effects of other investment frictions, e.g., “wedges,” or distortions, in Section 5.3.

<sup>29</sup>As above, we use lower-case to denote natural logs.

idiosyncratic component of productivity.

The two productivity components follow AR(1) processes (in logs):

$$\begin{aligned} x_{t+1} &= \rho_x x_t + \varepsilon_{t+1}, & \varepsilon_{t+1} &\sim \mathcal{N}(0, \sigma_\varepsilon^2) \\ \hat{z}_{it+1} &= \rho_z \hat{z}_{it} + \hat{\varepsilon}_{it+1}, & \hat{\varepsilon}_{it+1} &\sim \mathcal{N}(0, \sigma_{\hat{\varepsilon}}^2) . \end{aligned} \tag{7}$$

Thus, there are two sources of uncertainty at the firm level – aggregate uncertainty, with conditional variance  $\sigma_\varepsilon^2$ , and idiosyncratic uncertainty, with variance  $\sigma_{\hat{\varepsilon}}^2$ .

**Stochastic discount factor.** In line with the large literature on cross-sectional asset pricing in production economies, we parameterize directly the pricing kernel without explicitly modeling the consumer’s problem. In particular, we specify the SDF as

$$\begin{aligned} \log M_{t+1} &\equiv m_{t+1} = \log \rho - \gamma_t \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2 \\ \gamma_t &= \gamma_0 + \gamma_1 x_t , \end{aligned} \tag{8}$$

where  $\rho, \gamma_0 > 0$  and  $\gamma_1 \leq 0$  are constant parameters.<sup>30</sup> The SDF is determined by shocks to aggregate productivity. The conditional volatility of the SDF,  $\sigma_m = \gamma_t \sigma_\varepsilon$ , varies through time as determined by  $\gamma_t$ . This formulation allows us to capture in a simple manner a high, time-varying and countercyclical price of risk as observed in the data (since  $\gamma_1 < 0$ ,  $\gamma_t$  is higher following economic contractions, i.e., when  $x_t$  is negative). Additionally, directly parameterizing  $\gamma_0$  and  $\gamma_1$  enables the model to be quantitatively consistent with key moments of asset returns, which are important for our analysis. The risk free rate is constant and equal to  $-\log \rho$ . Thus,  $\gamma_0$  and  $\gamma_1$  only affect the properties of equity returns., easing the interpretation of these parameters. The maximum attainable Sharpe ratio is equal to the conditional standard deviation of the SDF, i.e.,  $SR_t = \gamma_t \sigma_\varepsilon$ , and the price of risk is equal to the square of the Sharpe ratio,  $\gamma_t^2 \sigma_\varepsilon^2$ .

**Input choices.** Firms hire labor period-by-period at a competitive wage,  $W_t$ . To keep the labor market simple, we assume that the equilibrium wage is given by

$$W_t = X_t^\omega ,$$

i.e., the wage is a constant elasticity and increasing function of aggregate productivity, where  $\omega \in [0, 1]$  determines the sensitivity of wages to aggregate conditions.<sup>31</sup> Maximizing over the

<sup>30</sup>This specification builds closely on those in, for example, Zhang (2005) and Jones and Tuzel (2013).

<sup>31</sup>This setup follows, for example, Belo et al. (2014) and İmrohoroğlu and Tüzel (2014).

static labor decision gives operating profits – revenues less labor costs – as

$$\Pi_{it} = GX_t^{\beta_i} Z_{it} K_{it}^\theta, \quad (9)$$

where  $G \equiv (1 - \theta_2) \theta_2^{\frac{\theta_2}{1-\theta_2}}$ ,  $\beta_i \equiv \frac{1}{1-\theta_2} (\hat{\beta}_i - \omega\theta_2)$ ,  $Z_{it} \equiv \hat{Z}_{it}^{\frac{1}{1-\theta_2}}$  and  $\theta \equiv \frac{\theta_1}{1-\theta_2}$ . The exposure of firm profits to aggregate conditions is captured by  $\beta_i$ , which is a simple transformation of the underlying exposure of firm productivity to the aggregate component,  $\hat{\beta}_i$ , and the sensitivity of wages,  $\omega$ .<sup>32</sup> The idiosyncratic component of productivity is similarly scaled, by  $\frac{1}{1-\theta_2}$ . The curvature of the profit function is equal to  $\theta$ , which depends on the relative elasticities of capital and labor in production. These scalings reflect the leverage effects of labor liabilities on profits. From here on, we will primarily work with  $z_{it}$ , which has the same persistence as  $\hat{z}_{it}$ , i.e.,  $\rho_z$ , and innovations  $\varepsilon_{it+1} = \frac{1}{1-\theta_2} \hat{\varepsilon}_{t+1}$  with variance  $\sigma_\varepsilon^2 = \left(\frac{1}{1-\theta_2}\right)^2 \sigma_{\hat{\varepsilon}}^2$ . We will also use the fact that  $\sigma_\beta^2 = \left(\frac{1}{1-\theta_2}\right)^2 \sigma_{\hat{\beta}}^2$ . Notice that the profit function takes precisely the form assumed in Section 2. Thus, the firm's dynamic investment problem takes the form in expression (1).

**Optimal investment.** The simplicity of this setting leads to exact analytical expressions for the firm's investment decision. Specifically, we show in Appendix B.2.1 that the firm's optimal investment policy is given by:

$$k_{it+1} = \frac{1}{1-\theta} (\tilde{\alpha} + \beta_i \rho_x x_t + \rho_z z_{it} - \beta_i \gamma_t \sigma_\varepsilon^2), \quad (10)$$

where  $\tilde{\alpha} \equiv \log \theta + \log G - \alpha$ ,  $\alpha \equiv r_f + \log(1 - (1 - \delta)\rho)$ .<sup>33</sup> The firm's choice of capital is increasing in  $x_t$  and  $z_{it}$  due to their direct effect on expected future productivity (i.e.,  $\beta_i \rho_x x_t + \rho_z z_{it} = \mathbb{E}_t[\beta_i x_{t+1} + z_{it+1}]$ ), but, *ceteris paribus*, firms with higher betas choose a lower level of capital. The magnitude of this effect is larger when  $\gamma_t$  is large, i.e., in economic downturns. Clearly, with risk neutrality, i.e.,  $\gamma_0 = \gamma_1 = 0$ , the last term is zero and investment is purely determined by expected productivity.

For a slightly different intuition, we substitute for  $\gamma_t$  and write the expression as

$$k_{it+1} = \frac{1}{1-\theta} (\tilde{\alpha} + \beta_i (\rho_x - \gamma_1 \sigma_\varepsilon^2) x_t + \rho_z z_{it} - \beta_i \gamma_0 \sigma_\varepsilon^2). \quad (11)$$

The risk premium affects the capital choice through both the time-varying and constant com-

<sup>32</sup>The adjustment term for labor supply,  $\omega\theta_2$ , has a small effect on the mean of the  $\beta$  distribution, but otherwise does not affect our analysis.

<sup>33</sup>More precisely, there are also terms that reflect the variance of shocks. Because these terms are negligible and play no role in our analysis (they are independent of the risk premium effects we measure), we suppress them here. The full expressions are given in Appendix B.2.1.

ponents of the price of risk: first, a more negative  $\gamma_1$  increases the responsiveness of firms to aggregate conditions. Intuitively, a high (low) realization of  $x_t$  has two effects – first, since  $x_t$  is persistent, it signals that productivity is likely to be high (low) in the future, increasing (decreasing) investment (this force is captured by the  $\rho_x$  term). Moreover, a high (low) realization of  $x_t$  implies a low (high) price of risk, which further increases (decreases) investment. Second, the constant component of the risk premium,  $\gamma_0$ , adds a firm-specific constant – i.e., a fixed-effect – which leads to permanent dispersion in firm-level capital.

**MPK dispersion.** By definition, the realized  $mpk$  is given by  $mpk_{it+1} = \log \theta + \pi_{it+1} - k_{it+1}$ . Substituting for  $k_{it+1}$ ,

$$mpk_{it+1} = \alpha + \varepsilon_{it+1} + \beta_i \varepsilon_{t+1} + \beta_i \gamma_t \sigma_\varepsilon^2, \quad (12)$$

and taking conditional expectations,

$$Empk_{it+1} \equiv \mathbb{E}_t [mpk_{it+1}] = \alpha + \beta_i \gamma_t \sigma_\varepsilon^2, \quad (13)$$

where  $\alpha$  is as defined in equation (10) and reflects the risk-free user cost of capital. Expression (12) shows that dispersion in the realized  $mpk$  can stem from uncertainty over the realization of shocks, as well as the risk premium term, which is persistent at the firm level and depends on (i) the firm’s exposure to the aggregate shock,  $\beta_i$  (and is increasing in  $\beta_i$ ), and (ii) the time  $t$  price of risk, which is reflected in the term  $\gamma_t \sigma_\varepsilon^2$ . Intuitively, firm-level  $mpk$  deviations are composed of both a transitory component due to uncertainty and a persistent component due to the risk premium. The transitory components are i.i.d. over time and lead to purely temporary deviations in  $mpk$  (even though the underlying productivity processes are autocorrelated); the risk premium, on the other hand, leads to persistent deviations – firms that are more exposed to aggregate shocks, and so are riskier, will have persistently high  $mpk$ .

Expression (13) hones in on this second force and shows the persistent effects of risk premia on the conditional expectation of time  $t+1$   $mpk$ , denoted  $Empk$ . Indeed, in this simple case, the ranking of firms’  $mpk$  will be constant in expectation as determined by the risk premium – high beta firms will have permanently high  $Empk$  and low beta firms the opposite. Importantly, the *value* of  $Empk$  will fluctuate with  $\gamma_t$ , but the ordering across firms will be preserved. This is the sense that we call this component persistent/permanent. Expression (12) shows that this ordering will not be preserved in realized  $mpk$  – due to the realization of shocks, the ranking of firms’  $mpk$  will fluctuate, but the firm-specific risk premium adds a persistent component.<sup>34</sup> Because the uncertainty portion of the realized  $mpk$  is always additively separable

---

<sup>34</sup>With additional adjustment frictions, there will be other factors confounding the relationship between beta and the realized and expected  $mpk$ .

and is independent of our mechanism, from here on we primarily work with  $Empk$ .

Expression (14) presents the cross-sectional variance of  $Empk$ :

$$\sigma_{Empk_t}^2 \equiv \sigma_{\mathbb{E}_t[mpk_{it+1}]}^2 = \sigma_\beta^2 (\gamma_t \sigma_\varepsilon^2)^2 . \quad (14)$$

Cross-sectional variation in  $Empk$  depends on the dispersion in beta and the price of risk. Dispersion will be greater when risk prices, reflected by  $\gamma_t \sigma_\varepsilon^2$ , are high and so will be countercyclical. The average long-run level of  $Empk$  dispersion is given by

$$E\sigma_{Empk}^2 \equiv \mathbb{E} [\sigma_{Empk_t}^2] = \sigma_\beta^2 (\gamma_0^2 + \gamma_1^2 \sigma_x^2) (\sigma_\varepsilon^2)^2 \quad \text{where} \quad \sigma_x^2 = \frac{\sigma_\varepsilon^2}{1 - \rho_x^2} . \quad (15)$$

An examination of expressions (13) and (14) confirms that the richer model here is consistent with the four key implications from Section 2, namely – (1) exposure to risk factors is a determinant of  $Empk$ ; (2) variation in the price of risk leads to predictable variation in mean  $Empk$ ; (3)  $mpk$  dispersion is related to beta dispersion; and (4)  $mpk$  dispersion is increasing in the price of risk, and so naturally contains a countercyclical element.

**Aggregate outcomes.** What are the implications of this dispersion in  $Empk$  for the aggregate economy? Appendix B.3 shows that aggregate output can be expressed as

$$\log Y_{t+1} \equiv y_{t+1} = a_{t+1} + \theta_1 k_{t+1} + \theta_2 n_{t+1} ,$$

where  $k_{t+1}$  denotes the aggregate capital stock,  $n_{t+1}$  aggregate labor and  $a_{t+1}$  the level of aggregate TFP, given by

$$a_{t+1} = a_{t+1}^* - \frac{1}{2} \frac{\theta_1 (1 - \theta_2)}{1 - \theta_1 - \theta_2} \sigma_{mpk,t+1}^2 , \quad (16)$$

where  $\sigma_{mpk,t+1}^2$  is realized  $mpk$  dispersion in period  $t + 1$ . The term  $a_{t+1}^*$  is the first-best level of TFP in the absence of any frictions (i.e., where marginal products are equalized). Thus, aggregate TFP monotonically decreases in the extent of capital “misallocation,” captured by  $\sigma_{mpk}^2$ . The effect of misallocation on aggregate TFP depends on the overall curvature in the production function,  $\theta_1 + \theta_2$  and the relative shares of capital and labor. The higher is  $\theta_1 + \theta_2$ , that is, the closer to constant returns to scale, the more severe the losses from mis-allocated resources. Similarly, fixing the degree of overall returns to scale, for a larger capital share,  $\theta_1$ , a given degree of misallocation has larger effects on aggregate outcomes.

Using equation (14), the conditional expectation of one-period ahead TFP is given by

$$\mathbb{E}_t [a_{t+1}] = \mathbb{E}_t [a_{t+1}^*] - \frac{1}{2} \frac{\theta_1 (1 - \theta_2)}{1 - \theta_1 + \theta_2} \sigma_\beta^2 (\gamma_t \sigma_\varepsilon^2)^2 . \quad (17)$$

The expression shows that risk premium effects unambiguously reduce aggregate TFP and disproportionately more so in business cycle downturns, since  $\gamma_t$  is countercyclical. Taking unconditional expectations gives the effects on the average long-run level of TFP in the economy:

$$\bar{a} \equiv \mathbb{E} [\mathbb{E}_t [a_{t+1}]] = a^* - \frac{1}{2} \frac{\theta_1 (1 - \theta_2)}{1 - \theta_1 + \theta_2} \sigma_\beta^2 (\gamma_0^2 + \gamma_1^2 \sigma_x^2) (\sigma_\varepsilon^2)^2 . \quad (18)$$

The expression directly links the extent of cross-sectional dispersion in required rates of return (which are in turn determined by the prices of risk and volatility of aggregate shocks) to the long-run level of aggregate productivity and gives a natural way to quantify the implications of these effects. Further, and perhaps more importantly, it uncovers a new connection between aggregate volatility and long-run economic outcomes, i.e., a “productivity cost” of business cycles – *ceteris paribus*, the higher is aggregate volatility ( $\sigma_\varepsilon^2$  and  $\sigma_x^2$  in the expression), the more depressed will be the average long-run level of TFP (relative to the frictionless first-best).

In Sections 6.1 and 6.2, we show that our model can be extended to include multiple risk factors and to allow  $\gamma_t$  to depend on additional factors beyond the state of technology and so expressions (17) and (18) provide a more general connection between financial conditions (that may be less than perfectly correlated with the real economy) and aggregate productivity. Thus, these expressions provide one way to link the rich findings of the literature on cross-sectional asset pricing to real allocations and measures of aggregate performance.

## 4.2 The Cross-Section of Expected Stock Returns and MPK

In this section, we derive a sharp link between a firm’s beta – and so its expected *mpk* – and its expected stock market return. This connection suggests an empirical strategy to measure the dispersion in beta and so quantify the *mpk* dispersion that arises from risk considerations using stock market data. Our key finding is that, to a first-order approximation, the firm’s expected stock return is a linear (and increasing) function of its beta.<sup>35</sup> Indeed, in the simple model outlined thus far, expected *mpk* is proportional to expected stock returns. This link, first, justifies our use of data on expected stock returns and stock market betas as a proxy for expected *mpk* in Section 3 and second, shows that the dispersion in expected stock returns puts tight empirical discipline on the dispersion in betas and so expected *mpk* arising from risk channels – indeed, under some circumstances, they are proportional to one another. We use this connection to provide transparent intuition for our numerical approach in Section 5.

We obtain an analytic approximation for expected stock market returns by log-linearizing around the non-stochastic steady state where  $X_t = Z_t = 1$ . To a first-order, the (log of the)

---

<sup>35</sup>It is well known that a first-order approximation may not be sufficient to capture risk premia. In our quantitative work in Section 5, we work with numerical higher order approximations.

expected excess stock return is equal to (derivations in Appendix B.4)

$$Er_{it+1}^e \equiv \log \mathbb{E}_t [R_{it+1}^e] = \psi \beta_i \gamma_t \sigma_\varepsilon^2, \quad (19)$$

where

$$\psi = \frac{\frac{1}{\rho} + \delta - 1}{\frac{1}{\rho} + \delta(1 - \theta) - 1} \frac{1 - \rho}{1 - \rho \rho_x + \rho \gamma_1 \sigma_\varepsilon^2}.$$

The expected excess return depends on the firm's beta (indeed, is linear and increasing in beta) and is increasing in the price of risk. Because the price of risk is countercyclical, risk premia increase during downturns for all firms and fall during expansions.<sup>36</sup> The time  $t$  cross-sectional dispersion in expected excess returns is given by

$$\sigma_{Er_t^e}^2 \equiv \sigma_{\log \mathbb{E}_t [R_{it+1}^e]}^2 = \psi^2 \sigma_\beta^2 (\gamma_t \sigma_\varepsilon^2)^2. \quad (20)$$

Similar to our findings for expected  $mpk$ , the expression reveals a tight link between beta dispersion and expected stock return dispersion. Indeed, if firms had identical betas, dispersion in expected returns would be zero. Moreover, as with expected  $mpk$  dispersion, expected stock return dispersion is increasing in the price of risk and so is countercyclical.

Comparing equations (13) and (19) shows that expected excess returns,  $Er_{it+1}^e$ , are proportional to expected  $mpk$ ,  $Empk_{it+1}$  and equations (14) and (20) show that  $\sigma_{Er_t^e}^2$  is proportional to  $\sigma_{Empk_t}^2$ . Thus, the expressions reveal a tight connection between cross-sectional variation in expected stock returns and expected  $mpk$  – both are dependent on the variation in betas. Although the exact proportionality will not hold in the full non-linear solution, we will use this intuition to quantify the role of risk considerations in generating dispersion in expected  $mpk$ .

Specifically, these results suggest an empirical strategy to estimate the three key structural parameters –  $\gamma_0$ ,  $\gamma_1$  and  $\sigma_\beta^2$  – using readily available stock market data. First, it is straightforward to verify that the market index – i.e., a perfectly diversified portfolio with no idiosyncratic risk – achieves the maximal Sharpe ratio:<sup>37</sup>

$$SR_{mt} = \gamma_t \sigma_\varepsilon, \quad ESR_m \equiv \mathbb{E} [SR_{mt}] = \gamma_0 \sigma_\varepsilon. \quad (21)$$

<sup>36</sup>Strictly speaking, these results hold in the approximation so long as  $1 - \rho \rho_x + \rho \gamma_1 \sigma_\varepsilon^2 > 0$ . This condition does not play a role in the numerical solution.

<sup>37</sup>The Sharpe ratio for an individual firm is  $SR_{it} = \frac{\beta_i \gamma_t \sigma_\varepsilon^2}{\sqrt{\left(\frac{1 - \rho \rho_x + \rho \gamma_1 \sigma_\varepsilon^2}{1 - \rho \rho_z}\right)^2 \sigma_\varepsilon^2 + \beta_i^2 \sigma_\varepsilon^2}}$ , which shows that, due to the presence of idiosyncratic risk, individual firms do not attain the maximum Sharpe ratio. However, in this linear environment, the diversified index faces no risk from  $\sigma_\varepsilon^2$ , so that the expression collapses to (21). Although in the full numerical solution the market may not exactly attain this value due to the nonlinear effects of idiosyncratic shocks, the expression highlights that the market Sharpe ratio is informative about  $\gamma_0$ .

The expression links the market Sharpe ratio to  $\gamma_0$ . Indeed, in this linearized environment, the mapping is one-to-one (given  $\sigma_\varepsilon^2$ ). Next, deriving equation (19) for the market index gives

$$Er_{mt+1} = \psi \bar{\beta} \gamma_t \sigma_\varepsilon^2, \quad Er_m \equiv \mathbb{E}[Er_{mt+1}] = \psi \bar{\beta} \gamma_0 \sigma_\varepsilon^2, \quad (22)$$

For given a value of  $\gamma_0$ , the equity premium is increasing as  $\gamma_1$  becomes more negative through its effects on  $\psi$  ( $\bar{\beta}$  denotes the mean beta across firms). Lastly, equation (20) connects dispersion in beta,  $\sigma_\beta^2$ , to dispersion in expected returns. Together, equations (20), (21) and (22) tightly link three observable moments of asset market data to the three parameters,  $\gamma_0$ ,  $\gamma_1$  and  $\sigma_\beta^2$ .

### 4.3 Adjustment Costs

In this section, we extend our framework to include capital adjustment costs. Although the main insights from the previous sections go through, we illustrate an important interaction between these costs and the effects of risk premia, namely, adjustment frictions amplify the impact of these systematic risk exposures on *mpk* dispersion.

We assume that capital investment is subject to quadratic adjustment costs, given by

$$\Phi(I_{it}, K_{it}) = \frac{\xi}{2} \left( \frac{I_{it}}{K_{it}} - \delta \right)^2 K_{it}.$$

With these costs, exact analytic solutions are no longer available. Appendix B.2.2 sets up the firm's problem and derives the log-linearized version of the firm's optimal investment policy:

$$k_{it+1} = \phi_{00} + \phi_1 \beta_i x_t + \phi_2 z_{it} + \phi_3 k_{it} - \phi_{01} \beta_i, \quad (23)$$

where

$$\begin{aligned} 0 &= \left( (\theta - 1) - \hat{\xi} (1 + \rho) \right) \phi_3 + \rho \hat{\xi} \phi_3^2 + \hat{\xi} \\ \phi_1 &= \frac{(\rho_x - \gamma_1 \sigma_\varepsilon^2) \phi_3}{\hat{\xi} (1 - \rho \rho_x \phi_3 + \rho \gamma_1 \sigma_\varepsilon^2 \phi_3)}, \quad \phi_2 = \frac{\rho_z \phi_3}{\hat{\xi} (1 - \rho \rho_z \phi_3)} \\ \phi_{01} &= \frac{\phi_3}{\hat{\xi} (1 - \rho \phi_3)} \frac{\gamma_0 \sigma_\varepsilon^2}{1 - \rho \rho_x \phi_3 + \rho \gamma_1 \sigma_\varepsilon^2 \phi_3}. \end{aligned}$$

We characterize the constant,  $\phi_{00}$ , in the Appendix.<sup>38</sup> The term  $\hat{\xi}$  is a composite parameter that captures the severity of adjustment costs, defined by  $\hat{\xi} \equiv \frac{\xi}{1 - \rho(1 - \delta)}$ .

Now, the past level of capital affects the new chosen level. The coefficient  $\phi_3$  captures the

---

<sup>38</sup>As above, we ignore terms reflecting variance adjustments that are close to zero.

strength of this relationship. It lies between zero and one and is increasing in the adjustment cost,  $\hat{\xi}$ . It is independent of the risk premium. The other coefficients each have a counterpart in equation (11), but are modified to reflect the influence of adjustment costs. The coefficients  $\phi_1$  and  $\phi_2$  are both decreasing in the adjustment cost – intuitively, adjustment costs reduce the responsiveness to shocks. As adjustment costs tend to infinity,  $\phi_3$  approaches one and the latter two coefficients go to zero. As adjustment costs become large, the firm’s choice of capital becomes more autocorrelated and eventually unresponsive to shocks. Importantly,  $\phi_{01}$  is increasing in these costs, showing that these additional adjustment frictions increase the importance of the firm’s beta in determining its choice of capital.<sup>39</sup>

The expression for  $\phi_{01}$  reveals an interaction between adjustment costs and time-varying risk – the denominator contains the product of  $\phi_3$  and  $\gamma_1$ , which implies that a more negative  $\gamma_1$  leads to higher values of  $\phi_{01}$  as long as adjustment costs are non-zero. Clearly this term disappears if adjustment costs are zero. In a moment, we will relate the value of  $\phi_{01}$  to *Empk* dispersion. Thus, this interaction effect will increase the impact of risk premia on that dispersion.

In this setting, both risk premium effects and adjustment costs lead to *Empk* dispersion (realized *mpk* dispersion also depends on uncertainty, as above). Closed-form solutions are not available for period-by-period dispersion. However, to gain intuition, we are able to characterize the mean of firm-level expected *mpk* (which is also the mean of realized *mpk*, since the shocks are mean-zero) and thus the dispersion in this mean component:

$$\mathbb{E}[Empk_{it+1}] = -\frac{1-\theta}{1-\phi_3}(\phi_{00} - \phi_{01}\beta_i) \Rightarrow \sigma_{\mathbb{E}[Empk_{it+1}]}^2 = \left(\frac{1-\theta}{1-\phi_3}\right)^2 \phi_{01}^2 \sigma_\beta^2. \quad (24)$$

Loosely speaking, the measure is the variance of the mean (i.e., permanent) component of firm-level *mpk* deviations. Recall that on their own, heterogeneous risk exposures only lead to persistent *mpk* deviations (in terms of the ordering across firms). These are exactly the effects we are picking up in (24). Further, we are particularly interested in this component, since the data show an important role for a highly persistent component in firm-level *mpk*. Notice also that  $\phi_{01}$  is multiplicative in  $\gamma_0$ ; in the absence of risk effects, there is no persistent *Empk* dispersion, even in the presence of adjustment costs.

Expression (24) shows that the extended model continues to give rise to *mpk* deviations that are persistent at the firm-level. Moreover, the expression reveals a second amplification effect of adjustment costs through the  $1 - \phi_3$  term in the denominator. Recall that  $\phi_3$  is increasing in these costs, as is  $\phi_{01}$ , so that holding fixed the other parameters, higher adjustment costs

---

<sup>39</sup>Strictly speaking, this is true so long as  $1 - \rho\rho_x\phi_3 + \rho\gamma_1\sigma_\varepsilon^2\phi_3 > 0$ . This condition holds for any reasonable level of adjustment costs, for example, given our estimates of the other parameters,  $\xi$  must be less than approximately 2180.

unambiguously increase risk effects on dispersion in  $Empk$ . An interesting implication of this result is that, perhaps surprisingly, adjustment frictions do not only affect transitory dispersion in the  $mpk$ . While this is true on their own, in conjunction with a fixed component in the  $mpk$ , which we have here, these frictions can serve to amplify the effects of that component.

Finally, how do adjustment costs change the relationship between expected  $mpk$ , beta and expected stock returns? Appendix B.4 shows that to a first-order, expected returns are not affected by adjustment costs and so the results from Section 4.2 continue to hold.<sup>40</sup> Thus, the arguments made in that section linking the key parameters of the model to moments of asset returns go through unchanged.

## 5 Quantitative Analysis

In this section, we use the analytical insights laid out above to numerically quantify the extent of  $mpk$  dispersion arising from risk premia effects.

### 5.1 Parameterization

We begin by assigning values to the more standard production parameters of our model. Following Atkeson and Kehoe (2005), we set the overall returns to scale in production  $\theta_1 + \theta_2$  to 0.85. We assume standard shares for capital and labor of 0.33 and 0.67, respectively, which gives  $\theta_1 = 0.28$  and  $\theta_2 = 0.57$ . These values imply  $\theta = 0.65$ .<sup>41</sup> We assume a period length of one year and accordingly set the rate of depreciation to  $\delta = 0.08$ . We estimate the adjustment cost parameter,  $\xi$ , in order to match the autocorrelation of investment, denoted  $\text{corr}(\Delta k_t, \Delta k_{t-1})$ , which is 0.38 in our data. Equation (32) in Appendix B.5 provides a closed-form expression for this moment, which reveals a tight connection with the severity of adjustment frictions.<sup>42</sup>

To estimate the parameters governing the aggregate shock process, we build a long sample of Solow residuals for the US economy using data from the Bureau of Economic Analysis on real GDP and aggregate labor and capital. The construction of this series is standard (details in Appendix A.4). With these data, we use a standard autoregression to estimate the parameters  $\rho_x$  and  $\sigma_\varepsilon^2$ . This procedure gives values of 0.94 and 0.0247 for the two parameters, respectively.<sup>43</sup>

---

<sup>40</sup>Although this is only exactly true under our first-order approximation, Table 7 verifies numerically that adjustment costs have relatively modest effects on moments of returns.

<sup>41</sup>This is close to the values generally used in the literature. For example, Cooper and Haltiwanger (2006) estimate a value of 0.59 for US manufacturing firms. David and Venkateswaran (2017) use a value of 0.62.

<sup>42</sup>The expression also reveals that for  $\rho_x$  close to  $\rho_z$ , which we find in the data, described next, the autocorrelation of within-firm investment is almost invariant to the firm's beta (indeed, the invariance is exact if  $\rho_x = \rho_z$ ). Thus, even with dispersion in betas, we may not see large variation in this moment across firms.

<sup>43</sup>The autoregression does not reject the presence of a unit root at standard confidence levels. We have also worked with the annual TFP series developed by John Fernald, available at:

Under our assumptions, firm-level productivity (including the aggregate component) can be measured directly (up to an additive constant) as  $y_{it} - \theta k_{it}$ . After controlling for the level of aggregate productivity, a similar autoregression on the residual (firm-specific) component yields values for  $\rho_z$  and  $\sigma_{\varepsilon}$  of 0.93 and 0.28, respectively.

Turning to the parameters of the SDF, we set  $\rho = 0.988$  to match an average annual risk-free rate of 1.2%. Following the arguments in Section 4.2, we estimate the values of  $\gamma_0$  and  $\gamma_1$  to match the post-war (1947-2017) average annual excess return on the market index of 7.7% and Sharpe ratio of 0.53.<sup>44</sup> This strategy is equivalent to matching both the mean and volatility of market excess returns (the standard deviation is 14.6%). To be comparable to the data, stock returns in the model need to be adjusted for financial leverage. To do so, we scale the mean and standard deviation of the model-implied returns by a factor of  $1 + \frac{D}{E}$  where  $\frac{D}{E}$  is the debt-to-equity ratio. We follow, e.g., Barro (2006) and assume an average debt-to-equity ratio of 0.5. Because both the numerator and denominator are scaled by the same constant, the Sharpe ratio is unaffected. For ease of interpretation, in what follows, we report the properties of levered returns. To compute the model-implied market return, we must also take a stand on the mean beta across firms. Assuming that the mean of  $\hat{\beta}_i$  (the underlying productivity beta) is one, and using the value of  $\omega$  (the sensitivity of wages to aggregate shocks) suggested by İmrohoroğlu and Tüzel (2014) of 0.20, we can compute the mean beta to be 1.99.<sup>45</sup> This is simply the mean productivity beta adjusted for the leverage effects of labor liabilities. This procedure yields values of  $\gamma_0 = 32$  and  $\gamma_1 = -140$ .

Finally, again following the insights in Section 4.2, we estimate the dispersion in betas to match the cross-sectional dispersion in expected stock returns. Because expected returns are not directly observable, we must choose an asset pricing model with which to estimate them. To be consistent with the broad literature, we use the expected returns predicted from the Fama-French model as computed in Section 3. We de-lever firm-level expected returns following the approach in Bharath and Shumway (2008) and Gilchrist and Zakrajsek (2012) (details in Appendix A.3). This procedure yields an estimated average within-industry standard deviation of un-levered expected returns of 0.127 (we report details and plot the full histogram of the expected return distribution in Appendix A.3: for example, the mean is about 9%, and the

---

<https://www.frbsf.org/economic-research/indicators-data/total-factor-productivity-tfp/>.

These data are only available for the more recent post-war period, but also show that the series is close to a random walk (i.e., the autocorrelation of growth rates is essentially zero). To address possible concerns about aggregation affecting the stochastic properties of these series (i.e., persistence and volatility), we have also constructed an alternative series directly from the firm-level data by averaging across the firms in each year. This gives results quite similar to the baseline,  $\rho_x = 0.92$  and  $\sigma_{\varepsilon} = 0.0245$ . Details are in Appendix A.4.

<sup>44</sup>We calculate these values using annualized monthly excess returns obtained from Kenneth French's website, [http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data\\_library.html](http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html).

<sup>45</sup>İmrohoroğlu and Tüzel (2014) estimate this value to match the cyclical of wages.

interquartile range is just under 12%; the standard deviation of raw expected returns, i.e., not de-levered or controlling for industry, is about 0.156).<sup>46</sup> Feeding this value into our quantitative model yields an estimate for  $\sigma_\beta$  of 12, and adjusting for the scaling  $1 - \theta_2$  gives the dispersion in underlying productivity betas,  $\sigma_{\hat{\beta}}$ , equal to 4.80.

To accurately capture the properties of the time-varying risk premium, we solve for returns numerically using a fourth-order approximation in Dynare++. We describe the details of the numerical procedure in Appendix C. In brief, for a given set of parameters, we use the model solution to simulate time series of excess returns and investment for a large panel of firms that differ in their betas. Averaging returns across these firms in each time period yields a series for the market return. We can then compute the mean and standard deviation (i.e., Sharpe ratio) of the market return. For each beta-type in each time period, we compute the expected excess return directly as the conditional expectation  $\mathbb{E}_t [R_{it+1}^e]$  and then average over the time periods to obtain the average expected return for a firm of that beta-type and the dispersion across types. For this set of parameters, we also compute the autocorrelation of investment. We then estimate the four parameters  $\gamma_0$ ,  $\gamma_1$ ,  $\sigma_\beta^2$  and  $\xi$  so that the results of this procedure leads to values of (i) market excess returns, (ii) market Sharpe ratio, (iii) cross-sectional dispersion in expected returns and (iv) the autocorrelation of investment that match their empirical counterparts.

Table 6 summarizes our empirical approach/results.

## 5.2 Risk-Based Dispersion in MPK

Table 7 presents our main quantitative results. We report four variants of our framework. The first column (“Baseline”) corresponds to our full model with time-varying risk and adjustment costs. In the second column (“Only Risk”), we report the effects of risk premia without adjustment costs (i.e., ignoring the interaction effects demonstrated above). The third column (“Constant Risk”) examines a version with adjustment costs but a constant price of risk (i.e.,  $\gamma_1 = 0$ ). The last column (“Only Constant Risk”) has a constant price of risk and no adjustment costs. Our goal in showing these different permutations is to understand the role that each element of our model plays in leading to various patterns in *mpk* dispersion.

**Long-run effects.** The first row of the table shows the average level of *mpk* dispersion that stems from heterogeneous risk exposures.<sup>47</sup> The second row shows the percentage of total

---

<sup>46</sup>Our estimates are consistent with those in Lewellen (2015), who reports moments of the expected return distribution from a number of predictive models. For example, using monthly data, he finds an annualized cross-sectional standard deviation of up to 17.5% (Model 3, Panel A, Table 5 of that paper).

<sup>47</sup>With adjustment costs, we do not have analytic expressions for period-by-period *Empk* dispersion. We compute these values using simulation and then average over them. Without adjustment costs, we can use expression (15) directly.

Table 6: Parameterization - Summary

Parameter	Description	Value
Production		
$\theta_1$	Capital share	0.28
$\theta_2$	Labor share	0.57
$\delta$	Depreciation rate	0.08
$\xi$	Adjustment cost	0.04
$\sigma_{\hat{\beta}}$	Std. dev. of risk exposures	4.80
Stochastic Processes		
$\rho_x$	Persistence of agg. shock	0.94
$\sigma_\varepsilon$	Std. dev. of agg. shock	0.0247
$\rho_z$	Persistence of idiosyncratic shock	0.93
$\sigma_{\tilde{\varepsilon}}$	Std. dev. of idiosyncratic shock	0.28
$\omega$	Wage elasticity	0.20
Stochastic Discount Factor		
$\rho$	Time discount rate	0.988
$\gamma_0$	SDF – constant component	32
$\gamma_1$	SDF – time-varying component	-140

observed misallocation that this value accounts for. In our sample, overall  $\sigma_{mpk}^2$  is 0.45. This is the denominator in that row. Next, we calculate the dispersion stemming from only the permanent component of firm-level MPK deviations (given by equation (24)), which we report in the third row of the table. To compute this value in the data, for each firm, we regress the time-series of its  $mpk$  on a firm-level fixed effect. The fixed-effect is the permanent component of firm-level  $mpk$  and the residuals transitory components. We then compute the variance of the permanent component, which yields a value of  $\sigma_{mpk}^2 = 0.30$ , about two-thirds of the total. This is the denominator in the fourth row of the table, which displays the model-implied permanent dispersion as a percentage of the observed permanent component in the data. The next row quantifies the implications of the estimated dispersion for the long-run level of aggregate TFP. It reports the gains in the average level of TFP from eliminating this source of  $mpk$  dispersion, denoted  $\Delta\bar{a}$ .<sup>48</sup> This is essentially an application of expression (16).

Column (1) shows that in the full model, risk premium effects lead to  $mpk$  dispersion of 0.17. This accounts for about 38% of overall  $mpk$  dispersion in the data. Of the model-implied dispersion, about 0.14 is permanent in nature, which explains about 47% of the permanent component in the data. The  $mpk$  dispersion arising from risk effects leads to a long-run TFP loss of about 7% (compared to an environment without risk premia, i.e., where  $\gamma_0 = \gamma_1 = 0$ ). These results suggest that (i) variation in firm-level risk exposures can generate significant MPK

<sup>48</sup>Note that this calculation does not mean that policies eliminating this source of  $mpk$  dispersion here would necessarily be desirable. We merely see this as a useful way to quantify the implications of our findings.

Table 7: Risk Premia and Misallocation

	Baseline	Only Risk	Constant Risk	Only Constant Risk
	(1)	(2)	(3)	(4)
MPK Implications				
$E\sigma_{Empk}^2$	0.17	0.05	0.16	0.05
% of total $\sigma_{mpk}^2$	37.9%	11.5%	35.9%	10.4%
$\sigma_{Empk}^2$	0.14	0.05	0.13	0.05
% of total $\sigma_{mpk}^2$	47.3%	15.7%	41.9%	15.7%
$\Delta\bar{a}$	0.07	0.02	0.07	0.02
$\text{corr}(\sigma_{Empk_t}^2, x_t)$	-0.31	-0.97	0.45	0.00
Moments				
$Er_m$	0.08	0.10	0.05	0.06
$ESR_m$	0.53	0.61	0.52	0.65
$\text{corr}(\Delta k_t, \Delta k_{t-1})$	0.38	-0.02	0.38	-0.03

dispersion, particularly when compared to the permanent component in the data, and (ii) the consequences for measures of aggregate performance such as TFP – i.e., the “productivity costs” of business cycles – can be substantial.

Column (2) shows that on their own (i.e., without adjustment costs), these exposures generate  $mpk$  dispersion of 0.05, which accounts for 11.5% of total  $\sigma_{mpk}^2$  in the data and they can explain about 16% of the permanent component. In other words, though the impacts of risk premia remain significant in isolation, they are less than half of those in column (1). These results highlight the important interactions with other adjustment frictions uncovered in Section 4.3 – in the first column, these effects are taken into account; in the second column, they are not. The associated TFP losses are also smaller, but remain significant, at approximately 2%.

Columns (3) and (4) show that the majority of these effects stems from the presence of a high persistent component in the price of risk, i.e.,  $\gamma_0$ , rather than from the time-variation from  $\gamma_1$ . Setting  $\gamma_1 = 0$  only modestly reduces the size of these effects in the presence of adjustment costs (compare columns (1) and (3)) and has a negligible effect on the results without them (columns (2) vs. (4)). The implication is that time-varying prices of risk do not add much to the long-run level of  $mpk$  dispersion.

**Countercyclical dispersion.** The last row in the top panel examines the second main implication of the theory, namely, the countercyclicality of  $mpk$  dispersion, which we measure as the correlation of  $\sigma_{Empk_t}^2$  with the state of the business cycle, i.e.,  $x_t$ . Column (1) shows that the full model generates significantly countercyclical dispersion in  $Empk$  – the correlation of  $\sigma_{Empk_t}^2$  with the state of the cycle is -0.31. To put this figure in context, Table 9 in Appendix A.2 shows

that the correlation between  $\sigma_{mpk}^2$  and the cyclical component of aggregate productivity in the data is -0.27. Thus, our quantitative model predicts countercyclical dispersion on par with this value. Column (2) shows that as the only factor behind *Empk* dispersion, the time-varying nature of risk premia would lead to an almost perfectly negative correlation with the business cycle. This is a clear implication of equation (14). The presence of adjustment costs in the first column confounds this relationship and leads to a smaller correlation (in absolute value) that is more in line with the data. Finally, the last two columns illustrate that time-varying risk is key to generating countercyclical dispersion. Without this element, *Empk* dispersion is significantly positive with adjustment costs and without them, is exactly acyclical. Thus, our findings suggest that the interaction of a countercyclical price of risk with adjustment frictions is crucial in yielding a negative (though far from negative one) correlation between *Empk* dispersion and the state of the business cycle.

To highlight the potential implications of the countercyclical *Empk* dispersion produced by our model, consider the connection with the empirical results in Eisfeldt and Rampini (2006), who show that firm-level dispersion measures tend to be countercyclical, yet most capital reallocation is procyclical. Our theory can – at least in part – reconcile this observation due to the countercyclical nature of factor risk prices and the high beta of high MPK firms: countercyclical reallocation would entail moving capital to the riskiest of firms in the riskiest of times. Thus, in light of our results, it may not be as surprising that countercyclical dispersion obtains, even in a completely frictionless environment.

**Moments.** In the bottom panel of Table 7, we investigate the role of each element in matching the target moments. Our full model in column (1) is directly parameterized to match the three moments, i.e., the equity premium, Sharpe ratio and autocorrelation of investment. In column (2), we show these moments from the version of our model without adjustment costs (i.e., setting  $\xi = 0$  and holding the other parameters at their estimated value). As implied by the approximation in Section 4.3, adjustment costs have a modest effect on the properties of returns (eliminating them raises the equity premium somewhat and the Sharpe ratio accordingly). However, the autocorrelation of investment falls dramatically without any adjustment frictions, indeed, becoming slightly negative (due to the mean-reverting nature of shocks). Thus, some degree of adjustment costs is crucial for matching this latter moment. Comparing columns (1) and (3) shows that without time-varying risk, the model struggles to match the equity premium, which falls almost by half, from about 8% to 5%. As implied by expressions (22), (21) and (32), time-varying risk is tightly linked to average excess returns, but has only modest effects on the average Sharpe ratio and the autocorrelation of investment. A similar pattern emerges from columns (2) and (4) – in the absence of adjustment costs, removing time-varying

risk significantly reduces the equity premium but has smaller effects on the other two moments.

In sum, the results in Table 7 show first, ex-ante firm-level variation in risk exposures lead to quantitatively important dispersion in  $mpk$ , with significant adverse effects on aggregate TFP; moreover, much of this dispersion is persistent and can account for a significant portion of what seems to be a puzzling pattern in the data, namely, persistent  $mpk$  deviations at the firm-level. Second, these exposures add a notably countercyclical element to  $mpk$  dispersion, going some way towards reconciling the countercyclical nature of firm-level dispersion measures.

### 5.3 Other Distortions

Recent work has pointed to a number of additional factors (beyond fundamentals and adjustment frictions) that may affect the firms’ investment decisions and lead to  $mpk$  dispersion, for example, financial frictions, variable markups or policy-induced distortions. Moreover, it has been pointed out that attempts to identify one of these forces – while abstracting from others – may yield misleading conclusions. This section demonstrates that our strategy of using asset market data is robust to this critique. In other words, our approach yields accurate estimates of risk premium effects, even in the presence of other, un-modeled, distortions.

We first follow the broad literature, e.g., Hsieh and Klenow (2009) and Restuccia and Rogerson (2008), and introduce these distortions as purely idiosyncratic “taxes” or “wedges” on firm revenues,  $1 - e^{\tau_{it+1}}$  (so that the firm keeps a portion  $e^{\tau_{it+1}}$ ). We work with the following specification for the wedge:

$$\tau_{it+1} = -\nu z_{it+1} - \eta_{it+1} . \tag{25}$$

The wedge is composed of two pieces. The first component is correlated with the firm’s idiosyncratic productivity, where the strength of the relationship is captured by  $\nu$ . If  $\nu > 0$ , the wedge discourages (encourages) investment by high (low) productivity firms. If  $\nu < 0$ , the opposite is true. The second component is uncorrelated with firm characteristics and can be either time-varying or fixed. Low (i.e., negative) values of  $\eta$  spur greater investment by firms irrespective of their underlying characteristics. We assume the firm knows the uncorrelated piece,  $\eta_{it+1}$ , when it chooses period  $t$  investment, i.e.,  $k_{it+1}$ . Further, we assume that both components of the wedge are uncorrelated with the firm’s beta. David and Venkateswaran (2017) show that this type of formulation can capture, for example, certain forms of financial frictions (due, e.g., to liquidity costs) and markups, in addition to policy-related distortions. We loosely refer to the wedge as a “distortion,” although we do not take a stand on whether it stems from efficient factors or not, simply that there are other frictions in the allocation process. Appendix B.6

derives the following expression for realized  $mpk$ :

$$mpk_{it+1} = \alpha + \varepsilon_{it+1} + \beta_i \varepsilon_{t+1} + \nu \rho_z z_{it} + \eta_{it+1} + \beta_i \gamma_t \sigma_\varepsilon^2, \quad (26)$$

The distortion has several effects on realized  $mpk$ . After the constant, the first two terms capture the effects of uncertainty over shocks and are identical to those in the baseline case. Next, the  $mpk$  includes a component that reflects the severity of the correlated distortion,  $\nu$ , and depends on the firm's expectations of its idiosyncratic productivity ( $\rho_z z_{it}$ ), leading to  $mpk$  deviations that are correlated with idiosyncratic productivity. Next, the  $mpk$  also depends on the uncorrelated component of distortions,  $\eta$ : firms with a high (positive) realization of  $\eta_{it+1}$  will invest less than their fundamentals would dictate, again leading to  $mpk$  deviations (that are uncorrelated with productivity). Finally, the last term reflects the risk premium, which, importantly, is independent of the distortions.

From expression (26), we can derive  $Empk$  and its cross-sectional variance:

$$Empk_{it+1} = \alpha + \nu \rho_z z_{it} + \eta_{it+1} + \beta_i \gamma_t \sigma_\varepsilon^2, \quad \Rightarrow \quad \sigma_{Empk_t}^2 = (\nu \rho_z)^2 \sigma_z^2 + \sigma_\eta^2 + \sigma_\beta^2 (\gamma_t \sigma_\varepsilon^2)^2. \quad (27)$$

Dispersion in  $Empk$  comes from three sources – first, the correlated component of the distortion,  $\nu$  (its contribution to  $mpk$  dispersion also depends on the cross-sectional variance of expected idiosyncratic productivity, which is the term in parentheses); second, the variance of the uncorrelated component; and third, the variation in the risk premium.

Turning to stock market returns on the other hand, Appendix B.6 proves that equation (19) still holds. In other words, expected stock returns are independent of idiosyncratic distortions. This result implies that the mapping from expected returns to beta is, to a first-order, unaffected by these other distortions, as is the mapping from beta dispersion to its effects on  $Empk$ . Thus, even in the richer environment here, featuring the additional sources of misallocation revealed in expressions (26) and (27), using stock market data continues to yield accurate estimates of the effects of heterogeneous risk exposures alone.

**Aggregate wedges.** In principle, we can allow the wedge to also be correlated with aggregate productivity,  $x_t$ . Consider first the following formulation:

$$\tau_{it+1} = -\nu_z z_{it+1} - \nu_x x_{t+1} - \eta_{it+1}.$$

Here, the parameter  $\nu_x$  captures the correlation of the distortion with the state of the business cycle. All firms are distorted by the aggregate component of the wedge, but all equally so. In this case, we can prove a similar result as with only idiosyncratic wedges – the distortion

does not affect the cross-sectional dispersion in expected stock returns and so that moment still accurately pins down the relevant risk exposures (the wedge also does not affect the dispersion in *Empk* coming from risk premium effects).<sup>49</sup>

As a second example, consider the following specification:

$$\tau_{it+1} = -\nu_z z_{it+1} - \nu_x \beta_i x_{t+1} - \eta_{it+1} .$$

Here, high beta firms are also disproportionately affected by the aggregate distortion. In this case, we can prove that expected return dispersion gives a lower bound on risk premium effects if the wedge worsens in downturns, i.e., if  $\gamma_x < 0$ , which may be a plausible conjecture. On the other hand, we could be at risk of overstating these effects if the wedge worsens in expansions, i.e.,  $\gamma_x > 0$ . However, it turns out that even in this case, our empirical results suggest a tight upper bound on the extent of the potential bias – specifically, the fact that *Empk* is countercyclical from prediction (2). To see this, we derive the following expression for *Empk*:

$$\begin{aligned} \mathbb{E}_t [mpk_{it+1}] &= \alpha + \nu_z \rho_z z_{it} + \nu_x \beta_i \rho_x x_t + (1 - \nu_x) \beta_i \gamma_t \sigma_\varepsilon^2 + \eta_{it+1} \\ &= \alpha + \nu_z \rho_z z_{it} + (\nu_x \rho_x + (1 - \nu_x) \gamma_1 \sigma_\varepsilon^2) \beta_i x_t + (1 - \nu_x) \beta_i \gamma_0 \sigma_\varepsilon^2 + \eta_{it+1} . \end{aligned}$$

The fact that *Empk* is countercyclical implies that the term in parentheses multiplying  $x_t$  should be negative, which puts the following bound on  $\nu_x$ :

$$\frac{\nu_x}{1 - \nu_x} < -\frac{\gamma_1 \sigma_\varepsilon^2}{\rho_x} .$$

Intuitively, a positive value of  $\nu_x$  adds a procyclical element to *Empk*. That *Empk* is actually countercyclical then puts a sharp bound on how large a positive value  $\nu_x$  can take. Using the parameter estimates from Section 5.1, the maximum value of  $\nu_x$  is about 0.08. In Appendix B.6 we derive an equation characterizing the potential bias in our estimate of *Empk* dispersion from a positive value of  $\nu_x$  – even at this upper bound, the bias would be quantitatively negligible.

## 5.4 Alternative Sources of Heterogeneity

Variation in betas across firms is an essential ingredient in our theory. Our empirical approach measures these betas using dispersion in firm-level expected returns. Here, we explore whether other forms of firm-level heterogeneity can quantitatively generate the significant return dispersion observed in the data. In other words, we ask whether our estimates of beta dispersion are picking up meaningful dispersion from other potential sources.

---

<sup>49</sup>The proofs for this section are in Appendix B.6.

First, we examine whether adjustment costs alone can generate substantial dispersion in conditional expected returns. To do so, we simulate a large panel of firms of a single beta-type (we set this to the mean value of beta). Although the firms are all of a single type, heterogeneity in conditional expected returns can arise from the presence of adjustment costs in combination with different histories of idiosyncratic shocks. The first column of Table 8 reports the results using the estimated value of  $\xi$ . The top row shows the minimum of the average of firm-level expected returns (i.e., we simulate a time series of conditional expected returns for each firm, compute the average for each firm and report the minimum), the second row the mean and the third row the maximum. Adjustment costs lead to very little dispersion in expected returns, e.g., the spread between the low and high firms is only about 0.1%.<sup>50</sup> To verify the robustness of this finding, column (2) repeats this analysis with a higher level of adjustment costs, namely,  $\xi = 3$ . The larger level of costs increases the level of expected returns slightly (recall that to a first-order, these costs should have no effects on the properties of expected returns) but has virtually no effect on the spread. Thus, it is unlikely that our estimates of beta are reflecting the effects of adjustment costs.

Table 8: Expected Return Dispersion – Other Forms of Heterogeneity

	Adjustment Costs					
	Estimated	Large	$\theta$	$\delta$	$\rho_z$	$\sigma_\varepsilon^2$
	(1)	(2)	(3)	(4)	(5)	(6)
Min. $\mathbb{E}[r_{it}]$	0.053	0.055	0.042	0.045	0.047	0.035
Mean $\mathbb{E}[r_{it}]$	0.054	0.056	0.054	0.054	0.054	0.054
Max. $\mathbb{E}[r_{it}]$	0.054	0.057	0.080	0.061	0.060	0.058
Spread	0.001	0.002	0.038	0.016	0.013	0.023

The remaining columns of Table 8 allow for variation in technological parameters across firms. Expression (19) provides some guidance as to the effects of some of these parameters on expected returns – taking derivatives, the expression implies that expected returns should be increasing in  $\theta$  and  $\delta$ . We also allow firms to differ in the properties of the stochastic process of idiosyncratic shocks,  $\rho_z$  and  $\sigma_\varepsilon^2$ . Although these do not influence expected returns under a

<sup>50</sup>This result should not be overly surprising – in the long run, the firms are identical, so mean expected returns should essentially be the same. We have also examined whether adjustment costs can lead to significant *transitory* dispersion in expected returns. To do so, we again simulate a large panel of firms with  $\beta = 1.99$  and then compute period-by-period dispersion in expected returns. The mean of the cross-sectional standard deviation is about 0.015 (and the maximum 0.03). This is relatively small compared to the observed standard deviation of expected returns of 0.127.

first-order approximation, there may be effects due to the nonlinearities in the numerical model.

Column (3) examines heterogeneity in  $\theta$ , the curvature of the profit function. Although there is little guidance on the extent of this heterogeneity (recall that all our estimations are within-industry), we compute expected returns for three values of  $\theta$ , namely 0.85 (our baseline), 0.95 and 0.75.<sup>51</sup> In line with the predictions of expression (19), expected returns are increasing in  $\theta$ . The first row reports the average expected return for a firm with low  $\theta$  (0.75), the second row the baseline and the third row a high  $\theta$  firm (0.95). The difference in mean expected returns between the highest and lowest  $\theta$  firms is about 4%. This is an economically significant spread, suggesting that large differences in this parameter can result in meaningful differences in firm-level risk premia. However, even this substantial degree of heterogeneity cannot account for the even larger differences in expected returns observed in the data – for example, Table 10 in Appendix A.3 shows that interquartile range of expected returns is almost 12%.

The last three columns show similar results for the remaining three parameters – the depreciation rate,  $\delta$ , and persistence and volatility of idiosyncratic shocks,  $\rho_z$  and  $\sigma_\varepsilon^2$ . Expected returns are increasing in the first (as suggested by (19)) and decreasing in the other two. We examine values of  $\rho_z$  ranging from 0.50 to 0.95. For the other two parameters, we report the average expected return when doubling or halving their baseline values (the second row always reports the baseline).<sup>52</sup> Even for these large differences in parameter values, the predicted spread in expected returns only ranges from 1.3% to 2.3%. Thus, a consistent message emerges across these experiments – unobserved heterogeneity in technological parameters seems unlikely to account for the large spreads in expected returns observed in the data.

## 5.5 Directly Measuring Productivity Betas

Our baseline approach to measuring firm-level risk exposures used the tight link between beta and expected stock returns laid out in Section 4.2. Here, we use an alternative strategy to estimate the dispersion in these exposures using only production-side data. In one sense, this approach is more direct – there is no need to employ firm-level stock market data to measure risk exposures. On the other hand, computing betas directly from production-side data has its drawbacks – the data are of a lower frequency (quarterly at best) and the time dimension of the panel is shorter. Further, it may be difficult to apply this method to firms in developing countries (where measured misallocation tends to be larger), since most firm-level datasets there have relatively short panels and are at the annual frequency. For those reasons, we view our results here as an informative check on our baseline findings above.

---

<sup>51</sup>To put these values in context, they loosely correspond to the range of values found in the literature. For example, İmrohoroglu and Tüzel (2014) use a value of 0.95. Clementi and Palazzo (2016) use 0.80.

<sup>52</sup>For  $\sigma_\varepsilon^2$ , we double or half the standard deviation,  $\sigma_\varepsilon$ , so the variance is scaled by a factor of four.

The approach is as follows. For each firm, we regress measured productivity growth, i.e.,  $\Delta z_{it} + \beta_i \Delta x_t$ , on aggregate productivity growth  $\Delta x_t$ . It is straightforward to verify that the coefficient from this regression is exactly equal to  $\beta_i$ . Using these estimates, we can compute the firm’s underlying productivity beta,  $\hat{\beta}_i$ , and calculate the cross-sectional dispersion in these estimates,  $\sigma_{\hat{\beta}}^2$ . We have applied this procedure using three different measures of the aggregate shock: (i) our long sample of Solow residuals, (ii) the series we construct from firm-level data (both of these are described in Section 5 and Appendix A.4) and (iii) the Fernald annual TFP series. The results yield values of  $\sigma_{\hat{\beta}}$  of 6.4, 4.3 and 5.9, respectively. Recall that our estimate for this value using stock return data was 4.8, which is in line with – and towards the lower end of – the range found here.

## 6 Extensions

The framework we have outlined thus far featured a tight connection between financial market conditions and the “real” side of the economy – indeed, the state of technology determined both the common component of firm-level productivities and the price of risk simultaneously. In this section, we generalize that setup to allow for more flexible formulations of the determinants of financial conditions. Although empirically disciplining the additional factors added here may be challenging, we demonstrate that the same insights from our baseline analysis go through.

### 6.1 Multifactor Model

In principle, it is straightforward to include multiple aggregate risk factors in our setting. Here, we lay out a simple extension along these lines and show that analogous results hold (details in Appendix B.7). There are  $J$  risk factors. The profits of each firm has a vector of loadings on these factors,  $\beta_i$ , where the  $j$ -th element of  $\beta_i$  is the loading of firm  $i$  on factor  $j$ . The exposure of the SDF to the factors is captured by a vector,  $\gamma$ , where element  $\gamma_j$  captures the exposure of the SDF to the  $j$ -th factor. For purposes of illustration, we assume  $\gamma$  is constant through time and there are no adjustment costs (these assumptions are easily relaxed). The covariance matrix of factor innovations is given by  $\Sigma_f$ . The realized  $mpk$  is equal to

$$mpk_{it+1} = \alpha + \varepsilon_{it+1} + \beta_i \varepsilon_{t+1} + \beta_i \Sigma_f \gamma' ,$$

where  $\varepsilon_{t+1}$  is the vector of shocks to these factors. Expected  $mpk$  and its cross-sectional dispersion are given by

$$\mathbb{E}_t [mpk_{it+1}] = \alpha + \beta_i \Sigma_f \gamma' , \quad \sigma_{\mathbb{E}_t [mpk_{it+1}]}^2 = \gamma \Sigma_f' \Sigma_{\beta} \Sigma_f \gamma' ,$$

where  $\Sigma_\beta$  is the covariance matrix of factor loadings across firms. This is the natural analog of expression (14): (i) expected  $mpk$  is determined by the firm’s exposure to (all) the aggregate risk factors in the economy and the risk prices of those factors, and (ii)  $mpk$  dispersion is a function of the dispersion in those exposures across firms as captured by  $\Sigma_\beta$ .

Next, we can derive the following approximations for expected excess stock returns and the cross-sectional dispersion in expected returns:

$$\log \mathbb{E}_t [R_{it+1}^e] = \beta_i \psi \Sigma_f \gamma', \quad \sigma_{\log \mathbb{E}_t [R_{it+1}^e]}^2 = \gamma \Sigma_f' \psi' \Sigma_\beta \psi \Sigma_f \gamma',$$

where  $\psi$  is a diagonal matrix with

$$\psi_{jj} = \frac{\frac{1}{\rho} + \delta - 1}{\frac{1}{\rho} + (1 - \theta) \delta - 1} \frac{1 - \rho}{1 - \rho \rho_j},$$

where  $\rho_j$  denotes the persistence of factor  $j$ . These are the analogs of expressions (19) and (20) – expected returns depend on factor exposures and the risk prices of those factors. Expected return dispersion depends on the dispersion in those exposures, here captured by  $\Sigma_\beta$ .

Thus, the same insights from the single factor model go through – dispersion in  $Empk$  and expected returns are both determined by variation in exposures to the set of aggregate factors and hence, there is a tight relationship between the two. To quantify the impact of these factors on  $mpk$  dispersion, however, we would need to know all the primitives governing the dynamics of the factors, e.g., the vector of persistences  $\rho$  and the covariance matrix  $\Sigma_f$ , and exposures, i.e., the exposures of the SDF,  $\gamma$ , and the vectors of firm loadings,  $\Sigma_\beta$ . This would likely entail taking a stand on the nature of each factor, computing their properties from the data and calibrating/estimating the  $\gamma$  vector and the covariance matrix of firm exposures,  $\Sigma_\beta$ .

## 6.2 Financial Shocks

Our baseline model tightly linked financial conditions, for example, the price of risk, to macroeconomic conditions, i.e., the state of aggregate technology. However, financial conditions may not co-move one-for-one with the “real” business cycle. Here, we extend the setup to include pure financial shocks. The stochastic discount factor takes the form

$$\begin{aligned} m_{t+1} &= \log \rho - \gamma_t \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2 \\ \gamma_t &= \gamma_0 + \gamma_f f_t, \end{aligned} \tag{28}$$

where

$$f_{t+1} = \rho_f f_t + \varepsilon_f, \quad \varepsilon_f \sim \mathcal{N}\left(0, \sigma_{\varepsilon_f}^2\right).$$

In this formulation,  $f_t$  denotes the time-varying state of financial conditions, which is now disconnected from the state of aggregate technology. These financial factors may be correlated with real conditions,  $x_t$ , but need not be perfectly so. Thus, there is scope for changes in financial conditions, independent of those in real conditions, to affect the price of risk and through this channel, the allocation of capital.<sup>53</sup> Note the difference between this setup and the one in Section 6.1 – here, the financial factor,  $f_t$ , does not directly enter the profit function of the firm, it only affects the price of risk. Thus, it is a shock purely to financial market conditions. In contrast, the factors considered in Section 6.1 directly affected firm profitability.

Keeping the remainder of the environment the same as Section 4, we can derive exactly the same expressions for expected  $mpk$  and its cross-sectional variance, i.e.,

$$\mathbb{E}_t [mpk_{it+1}] = \alpha + \beta_i \gamma_t \sigma_\varepsilon^2, \quad \sigma_{\mathbb{E}_t [mpk_{it+1}]}^2 = \sigma_\beta^2 (\gamma_t \sigma_\varepsilon^2)^2,$$

where now  $\gamma_t$  is a function of financial market conditions. When credit market conditions tighten (i.e., when  $f_t$  is small/negative since  $\gamma_f < 0$ ),  $\gamma_t$  is high and  $mpk$  dispersion will rise. Finally, the average long-run level of  $Empk$  dispersion and aggregate productivity are given by

$$\mathbb{E} [\sigma_{Empk_t}^2] = \sigma_\beta^2 (\gamma_0^2 + \gamma_f^2 \sigma_f^2) (\sigma_{\varepsilon_f}^2)^2, \quad \bar{a} = a^* - \frac{1}{2} \frac{\theta_1 (1 - \theta_2)}{1 - \theta_1 - \theta_2} \sigma_\beta^2 (\gamma_0^2 + \gamma_f^2 \sigma_f^2) (\sigma_{\varepsilon_f}^2)^2,$$

where  $\sigma_f^2 = \frac{\sigma_{\varepsilon_f}^2}{1 - \rho_f^2}$ . The expressions reveal a tight connection between financial conditions and long-run performance of the economy – higher financial volatility ( $\sigma_{\varepsilon_f}^2$ ), even independent of the state of the macroeconomy, induces greater persistent MPK dispersion and depresses the average level of achieved productivity.

## 7 Conclusion

In this paper, we have revisited the notion of “misallocation” from the perspective of a risk-sensitive, or risk-adjusted, version of the stochastic growth model with heterogeneous firms. The standard optimality condition for investment in this framework suggests that expected firm-level marginal products should reflect exposure to factor risks, and their pricing. To the extent that firms are differentially exposed to these risks, as the literature on cross-sectional asset pricing suggests, the implication is that cross-sectional dispersion in MPK may not only reflect

---

<sup>53</sup>Our baseline model is the nested case where  $\gamma_f = \gamma_1$  and  $f_t$  and  $x_t$  are perfectly correlated.

true misallocation, but also risk-adjusted capital allocation. We provide empirical support for this proposition and demonstrate that a suitably parameterized model of firm-level investment behavior suggests that, indeed, risk-adjusted capital allocation accounts for a significant fraction of observed MPK dispersion among US firms. Importantly, much of this dispersion is persistent in nature, which speaks to the large portion of observed MPK dispersion that arises from seemingly persistent/permanent sources. Further, our setup leads to a novel link between aggregate volatility, cross-sectional asset pricing and long-run productivity – our results suggest that there can be substantial “productivity costs” of business cycles.

There are several promising directions for future research. Our framework points to a new connection between business cycle dynamics and the cross-sectional allocation of inputs. Further investigation of this link, for example, a deeper exploration of the sources of beta variation across firms, would lead to a better understanding of the underlying causes of observed marginal product dispersion. The tractability of our setup allowed us to quantify the effects of financial market considerations, e.g., cross-sectional variation in required rates of return, on measures of economic performance, i.e., aggregate TFP. This link should be useful beyond the misallocation literature and provides a new way to evaluate the implications of the rich set of empirical findings in cross-sectional asset pricing. For example, pursuing multifactor/financial shock extensions of our analysis (e.g., along the lines laid out in Sections 6.1 and 6.2) to incorporate the many risk factors pointed out in that literature would be fruitful to measure the implications of those factors for allocative efficiency and further assess the role of risk considerations in leading to misallocation. Of particular interest would be whether those factors are efficient or not, e.g., to what extent do capital allocations reflect the “mispricing” of assets.

# Appendix

## A Data

In this appendix, we describe the various data sources used throughout our analysis.

### A.1 Compustat/CRSP

We obtain firm-level data from COMPUSTAT and CRSP. We include firms coded as industrial firms from 1965-2015. Our time-series regressions and portfolio sorts use data from 1973-2015, since data on the GZ spread and EB premium begin in 1973 and because there are relatively few industries with at least 10 firms in a given year pre-1973.<sup>54</sup> We further exclude financial firms by dropping those with COMPUSTAT SIC codes that correspond to finance, insurance, and real estate (FIRE, SIC codes 6000-6999). We also exclude firms with missing SIC codes or coded as non-classifiable, as much of our analysis examines within-industry variables. We measure firm revenue using sales from Compustat (series SALE), and capital using the depreciated value of plant, property, and equipment (series PPENT). We measure firm marginal product of capital in logs (up to an additive constant) as the difference between log revenue and capital,  $mpk_{it} = y_{it} - k_{it}$ . Market capitalization is measured as the price times shares outstanding from CRSP and profitability as the ratio of earnings before interest, taxes, depreciation, and amortization (EBITDA) divided by book assets (AT). We measure market leverage as the ratio of book debt to the sum of market capitalization plus book debt, where book debt is measured as current liabilities (LCT) + 1/2 long term debt (DLTT), following Gilchrist and Zakrajsek (2012). We measure book-to-market as the ratio of book equity to the market capitalization of the firm, where we measure book equity as the sum of shareholder's equity (SEQ), deferred taxes and investment credit (TXDITC) and the preferred stock liquidating value (PSTKL).

**Computation of betas and expected returns.** Here, we describe our procedure to compute stock market betas, MPK betas and expected returns.

We estimate stock market betas by performing time-series regressions of firm-level excess returns (realized returns from CRSP in excess of the risk-free rate),  $r_{it}^e$ , on aggregate factors, denoted by the  $N \times 1$  vector  $\mathbf{F}_t$ . For each firm, the specification takes the form

$$r_{it}^e = \alpha_{i\tau} + \beta_{i\tau} \mathbf{F}_t + \epsilon_{it} \quad (29)$$

---

<sup>54</sup>The portfolio sorts are qualitatively similar if we use data from the full 1965-2015 sample.

We estimate these regressions (and the MPK betas described below) at the quarterly frequency using backwards-looking five-year rolling windows, i.e., for  $t \in \{\tau - N_\tau + 1, \tau - \tau_T + 2, \dots, \tau\}$ , where  $\beta_{i\tau}$  denotes the  $1 \times N$  vector of factor loadings and  $N_\tau$  the length of the window.<sup>55</sup> Under the CAPM, the single risk factor is the aggregate market return. Under the Fama-French 3 factor model, the risk factors are the market return (MKT), the return on a portfolio that is long in small firms and short in large ones (SMB) and the return on a portfolio that is long in high book-to-market firms and short on low ones (HML).

To obtain a single measure of risk exposure from the multi-factor Fama-French model, we combine the betas into a single value using estimated prices of risk from Fama and MacBeth (1973) regressions. Specifically, we estimate the following cross-sectional regression in each period:

$$r_{it}^e = \alpha_t + \lambda_t \beta_{it} + \epsilon_{it} \quad (30)$$

where  $\lambda_t$  denotes the  $1 \times N$  vector of period  $t$  factor risk prices and  $\beta_{it}$  the  $N \times 1$  vector of exposures, estimated as just described. We then calculate a single index of exposure to these factors as

$$\beta_{it,FF} = \lambda \beta_{it} = \sum_x \lambda_x \beta_{it,x}, \quad x \in MKT, HML, SMB$$

where  $\lambda_x = \frac{1}{T} \sum_{t=1}^T \lambda_{xt}$ .

We follow an analogous procedure to estimate MPK betas, simply replacing excess stock market returns on the left-hand side of (29) and (30) with  $mpk_{it}$ . The first regression yields measures of  $\beta_{MPK}$ , i.e., the exposure of each firm's MPK to the aggregate risk factors. The second regression combines these exposures into a single value in the multifactor model, using the coefficients from cross-sectional Fama and MacBeth (1973) regressions, which play the role of factor risk prices in determining the relationship between risk exposures and the cross-section of expected MPK.

Finally, we estimate expected stock returns as the predicted values from the cross-sectional asset pricing equation

$$r_{it}^e = \alpha_i + \lambda \beta_{it} + \epsilon_{it}$$

i.e., as  $\alpha_i + \lambda \beta_{it}$ , where  $\beta_{it}$  is as estimated from equation (29),  $\lambda$  is calculated using the estimates from (30) as described above, and  $\alpha_i$  is calculated as  $\alpha_i = \frac{1}{T} \sum_{t=1}^T (\alpha_{it} + \epsilon_{it})$  also using the estimates from (30).

---

<sup>55</sup>We have also estimated the stock market betas using higher frequency monthly data (and two-year rolling windows) and obtained similar results.

**Composition-adjusted measures of mean and dispersion.** For Predictions 2 and 4, we compute time-series of the mean and cross-sectional dispersion in MPK. Because Compustat is an unbalanced panel with significant changes in the composition of firms over time, it is important to ensure that we measure the variation in these objects due to changes in firm MPK, rather than additions or deletions from the dataset (especially since many additions and deletions to the Compustat data may not be true firm entry or exit). We therefore compute composition-adjusted measures of the mean and cross-sectional standard deviation in MPK that are only affected by firms who continue on in the dataset. We use the following procedure:

For each set of adjacent periods, e.g.,  $t$  and  $t + 1$ , we compute the statistic of interest in each time period (i.e., mean or cross-sectional standard deviation) only for those firms that are present in the data in both periods. Taking the difference yields the change in the statistic from time  $t$  to  $t + 1$  that is due only to changes in the common set of firms. Completing this procedure yields time-series of changes in the mean and cross-sectional standard deviation of MPK. We then combine these time-series of changes with the initial values of the statistics of interest (across all firms in the initial period) to construct a synthetic series for each statistic, which is not affected by the changing composition of firms in the data.

## A.2 Time-Series Correlations

Table 9 reports contemporaneous correlations between (within-industry) MPK dispersion and indicators of the price of risk and the business cycle.

Table 9: Correlations of MPK Dispersion, the Price of Risk and the Business Cycle

	MPK Dispersion	PD Ratio	GZ Spread	EB Premium	GDP	TFP
MPK Dispersion	1.00					
PD Ratio	-0.42	1.00				
GZ Spread	0.39	-0.51	1.00			
EB Premium	0.51	-0.57	0.68	1.00		
GDP	-0.53	0.46	-0.59	-0.66	1.00	
TFP	-0.27	0.43	-0.32	-0.44	0.70	1.00

*Notes:* This table reports time-series correlations of MPK dispersion, measures of the price of risk and the business cycle. MPK dispersion is measured as the within-industry standard deviation in *mpk*. The PD ratio is the aggregate stock market price/dividend ratio. The GZ spread and EB (excess bond) premium are measures of credit spreads. GDP is log GDP and TFP is log TFP. We extract the cyclical components of GDP, TFP and the PD ratio using a one-sided Hodrick-Prescott filter. All series are described in more detail in the main text and Appendix A. All data are quarterly and are from 1973-2015.

### A.3 Expected Return Distribution

Table 10 reports statistics from the cross-sectional distribution of expected returns ( $E[r^e]$ ) and unlevered expected returns ( $E[r^a]$ ), which is a measure of expected asset returns. We de-lever expected returns using an adjustment factor computed from Black-Scholes following the approach in, e.g., Bharath and Shumway (2008) and Gilchrist and Zakrajsek (2012). Specifically, we implement an iterative procedure using data on realized equity volatility, firm debt, and firm market capitalization to compute the implied value of assets and asset volatility. The Black-Scholes equations imply  $\mathbb{E}[r^a] \approx \frac{Mkt. cap.}{V_A} \Phi(\delta_1) \mathbb{E}[r^e]$ , where  $V_A$  is the total firm asset value implied by Black-Scholes as a function of the market capitalization of equity, book debt, and realized backwards-looking equity volatility and  $\Phi(\delta_1)$  is the Black-Scholes “delta” of equity, as defined in, e.g., Gilchrist and Zakrajsek (2012). We compute the adjustment factor  $\frac{Mkt. cap.}{V_A} \Phi(\delta_1)$  for each firm using daily data and a 21 day backwards-looking window for equity volatility and then calculate a firm-year adjustment factor by averaging this adjustment factor for each firm-year. Finally, we compute un-levered expected returns for each firm as the product of its expected equity return multiplied by this factor. To find the cross-sectional distribution of within-industry expected returns, we de-mean expected returns by industry-year, keeping industry-years with at least 10 observations. We then add back the means and report the resulting distribution.<sup>56</sup> Figure 1 plots the full cross-sectional distribution of within-industry expected excess asset and equity returns.

Table 10: The Distribution of Expected Excess Returns

Percentile	10th	25th	Mean	75th	90th	Std. Dev.
Panel A: Not Industry-Adjusted						
$E[r^a]$	-3.6%	4.0%	9.8%	17.1%	24.7%	13.2%
$E[r^e]$	-5.3%	6.6%	12.1%	20.6%	28.6%	15.6%
Panel B: Industry-Adjusted						
$E[r^a]$	-3.6%	4.7%	9.8%	16.6%	23.6%	12.7%
$E[r^e]$	-4.6%	6.6%	12.1%	20.3%	28.1%	15.0%

*Notes:* This table reports the cross-sectional distributions of un-levered expected excess equity returns,  $E[r^a]$ , and expected excess equity returns,  $E[r^e]$ . Industry adjustment is done by demeaning each measure of expected returns by industry-year. We then add back the mean returns to these distributions.

<sup>56</sup>The results are similar if we compute our cross-sectional statistics within each year or industry-year and average over the years/industry-years

Figure 1: Cross-Sectional Distribution of Expected Excess Returns

*Notes:* This figure displays the cross-sectional distributions of un-levered expected excess equity returns,  $E[r^a]$ , and expected excess equity returns,  $E[r^e]$ . Industry adjustment is done by demeaning each measure of expected returns by industry-year. We then add back the mean returns to these distributions. The vertical bars denote the histograms of these distributions, while the solid lines are the results of kernel smoothing regressions with a bandwidth of 0.25.

## A.4 Aggregate Productivity Series

**Solow residuals.** To build a series of Solow residuals, we obtain data on real GDP and aggregate labor and capital from the Bureau of Economic Analysis. Data on real GDP are from BEA Table 1.1.3 (“Real Gross Domestic Product”), data on labor are from BEA Table 6.4 (“Full-Time and Part-Time Employees”) and data on the capital stock are from BEA Table 1.2 (“Net Stock of Fixed Assets”). The data are available annually from 1929-2016. With these data we compute  $x_t = y_t - \theta_1 k_t - \theta_2 n_t$ . We extract a linear time-trend and then estimate the autoregression in equation (7).

**Firm-level series.** To construct the alternative series for aggregate productivity from the firm-level data, we use the following procedure. First, we compute firm-level productivity as  $z_{it} + \beta_i x_t = y_{it} - \theta k_{it}$ . We then average these values across all firms in each year. Because  $z_{it}$  is mean-zero and independent across firms, this yields a scaled measure of aggregate productivity,  $\bar{\beta} x_t$ , where  $\bar{\beta}$  is the mean beta across firms, which under our assumptions, is approximately two. We extract a linear time-trend from this series and then estimate the autoregression. The coefficient from this regression gives  $\rho_x$ . The standard deviations of the residuals gives  $\bar{\beta} \sigma_\varepsilon$  and after dividing by  $\bar{\beta}$  gives the true volatility of shocks. Applying this procedure to the set of Compustat firms over the period 1962-2016 yields values of  $\rho_x = 0.92$  and  $\sigma_\varepsilon = .0245$ .

## B Derivations and Proofs

This appendix provides detailed derivations for the expressions in the text.

### B.1 Motivation

**Derivation of equation (3).**

$$\begin{aligned} 1 &= \mathbb{E}_t [M_{t+1} (MPK_{it+1} + 1 - \delta)] \\ &= \mathbb{E}_t [M_{t+1}] \mathbb{E}_t [MPK_{it+1} + 1 - \delta] + \text{cov} (M_{t+1}, MPK_{it+1}) \end{aligned}$$

Consider the *MPK* of a ‘risk-free’ firm defined by  $\text{cov} (M_{t+1}, MPK_{ft+1}) = 0$ . We have

$$1 = \mathbb{E}_t [M_{t+1}] (MPK_{ft+1} + 1 - \delta)$$

and combining,

$$\begin{aligned} \mathbb{E}_t [MPK_{it+1}] &= MPK_{ft+1} - \frac{\text{cov} (M_{t+1}, MPK_{it+1})}{\mathbb{E}_t [M_{t+1}]} \\ &= \alpha_t + \beta_{it} \lambda_t \end{aligned}$$

where  $\alpha_t$ ,  $\beta_{it}$  and  $\lambda_t$  are as defined in the text.. By a no-arbitrage condition, it must be the case that  $\frac{1}{\mathbb{E}_t [M_{t+1}]} = MPK_{ft+1} + 1 - \delta = R_{ft}$  where  $R_{ft}$  is the gross risk-free interest rate.

**No aggregate risk.** With no aggregate risk,  $M_{t+1} = \rho \forall t$  where  $\rho$  is the rate of time discount. The Euler equation gives

$$1 = \rho (\mathbb{E}_t [MPK_{it+1}] + 1 - \delta) \forall i, t \quad \Rightarrow \quad \mathbb{E}_t [MPK_{it+1}] = \frac{1}{\rho} - (1 - \delta) = r_f + \delta$$

**CAPM.** Clearly,  $-\text{cov} (M_{t+1}, MPK_{it+1}) = b \text{cov} (R_{mt+1}, MPK_{it+1})$  and  $\text{var} (M_{t+1}) = b^2 \text{var} (R_{mt+1})$ . Since the market return is an asset, it must satisfy  $\mathbb{E}_t [R_{mt+1}] = R_{ft} + \frac{\lambda_t}{b}$  so that  $\lambda_t = b (\mathbb{E}_t [R_{mt+1}] - R_{ft})$ . Substituting into expression (3) gives the CAPM expression in the text.

**CCAPM.** A log-linear approximation to the SDF around its unconditional mean gives  $M_{t+1} \approx \mathbb{E} [M_{t+1}] (1 + m_{t+1} - \mathbb{E} [m_{t+1}])$  and in the case of *CRRA* utility,  $m_{t+1} = -\gamma \Delta c_{t+1}$  where  $\Delta c_{t+1}$  is log consumption growth. Substituting for  $M_{t+1}$  into expression (3) gives the CCAPM expression in the text.

## B.2 Model Solution

### B.2.1 Baseline Environment

The static labor choice solves

$$\max e^{\hat{z}_{it} + \hat{\beta}_i x_t} K_{it}^{\theta_1} N_{it}^{\theta_2} - W_t N_{it}$$

with the associated first order condition

$$N_{it} = \left( \frac{\theta_2 e^{\hat{z}_{it} + \hat{\beta}_i x_t} K_{it}^{\theta_1}}{W_t} \right)^{\frac{1}{1-\theta_2}}$$

Substituting for the wage with  $W_t = X_t^\omega$  and rearranging gives operating profits

$$\Pi_{it} = G e^{\beta_i x_t + z_{it}} K_{it}^\theta$$

where  $G \equiv (1 - \theta_2) \theta_2^{\frac{\theta_2}{1-\theta_2}}$ ,  $\beta_i = \frac{1}{1-\theta_2} (\hat{\beta}_i - \omega \theta_2)$ ,  $z_{it} = \frac{1}{1-\theta_2} \hat{z}_{it}$  and  $\theta = \frac{\theta_1}{1-\theta_2}$ , which is equation (9) in the text.

The first order and envelope conditions associated with (1) give the Euler equation:

$$\begin{aligned} 1 &= \mathbb{E}_t [M_{t+1} (\theta e^{z_{it+1} + \beta_i x_{t+1}} G K_{it+1}^{\theta-1} + 1 - \delta)] \\ &= (1 - \delta) \mathbb{E}_t [M_{t+1}] + \theta G K_{it+1}^{\theta-1} \mathbb{E}_t [e^{m_{t+1} + z_{it+1} + \beta_i x_{t+1}}] \end{aligned}$$

Substituting for  $m_{t+1}$  and rearranging,

$$\begin{aligned} \mathbb{E}_t [e^{m_{t+1} + z_{it+1} + \beta_i x_{t+1}}] &= \mathbb{E}_t \left[ e^{\log \rho - \gamma_t \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2 + z_{it+1} + \beta_i x_{t+1}} \right] \\ &= \mathbb{E}_t \left[ e^{\log \rho + \rho_z z_{it} + \varepsilon_{it+1} + \beta_i \rho_x x_t + (\beta_i - \gamma_t) \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2} \right] \\ &= e^{\log \rho + \rho_z z_{it} + \beta_i \rho_x x_t + \frac{1}{2} \sigma_\varepsilon^2 + \frac{1}{2} \beta_i^2 \sigma_\varepsilon^2 - \beta_i \gamma_t \sigma_\varepsilon^2} \end{aligned}$$

and

$$\mathbb{E}_t [M_{t+1}] = \mathbb{E}_t \left[ e^{\log \rho - \gamma_t \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2} \right] = e^{\log \rho + \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2 - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2} = \rho$$

so that

$$\theta G K_{it+1}^{\theta-1} = \frac{1 - (1 - \delta) \rho}{e^{\log \rho + \rho_z z_{it} + \beta_i \rho_x x_t + \frac{1}{2} \sigma_\varepsilon^2 + \frac{1}{2} \beta_i^2 \sigma_\varepsilon^2 - \beta_i \gamma_t \sigma_\varepsilon^2}}$$

and rearranging and taking logs,

$$k_{it+1} = \frac{1}{1 - \theta} \left( \tilde{\alpha} + \frac{1}{2} \sigma_\varepsilon^2 + \frac{1}{2} \beta_i^2 \sigma_\varepsilon^2 + \rho_z z_{it} + \beta_i \rho_x x_t - \beta_i \gamma_t \sigma_\varepsilon^2 \right)$$

where

$$\begin{aligned}\tilde{\alpha} &= \log \theta + \log G - \alpha \\ \alpha &= -\log \rho + \log (1 - (1 - \delta) \rho) = r_f + \log (1 - (1 - \delta) \rho)\end{aligned}$$

Ignoring the variance terms gives equation (10).

The realized  $mpk$  is given by

$$\begin{aligned}mpk_{it+1} &= \log \theta + \pi_{it+1} - k_{it+1} \\ &= \log \theta + \log G + z_{it+1} + \beta_i x_{t+1} - (1 - \theta) k_{it+1} \\ &= \log \theta + \log G + z_{it+1} + \beta_i x_{t+1} - \tilde{\alpha} - \rho_z z_{it} - \beta_i \rho_x x_t + \beta_i \gamma_t \sigma_\varepsilon^2 \\ &= \alpha + \varepsilon_{it+1} + \beta_i \varepsilon_{t+1} + \beta_i \gamma_t \sigma_\varepsilon^2\end{aligned}$$

The time  $t$  conditional expected  $mpk$  is

$$\mathbb{E}_t [mpk_{it+1}] = \alpha + \beta_i \gamma_t \sigma_\varepsilon^2$$

and the time  $t$  and mean cross-sectional variances are, respectively,

$$\begin{aligned}\sigma_{\mathbb{E}_t[mpk_{it+1}]}^2 &= \sigma_\beta^2 (\gamma_t \sigma_\varepsilon^2)^2 \\ \mathbb{E} \left[ \sigma_{\mathbb{E}_t[mpk_{it+1}]}^2 \right] &= \mathbb{E} \left[ \sigma_\beta^2 (\gamma_0 + \gamma_1 x_t)^2 (\sigma_\varepsilon^2)^2 \right] = \sigma_\beta^2 (\gamma_0^2 + \gamma_1^2 \sigma_x^2) (\sigma_\varepsilon^2)^2\end{aligned}$$

## B.2.2 Adjustment Costs

With capital adjustment costs, the firm's investment problem takes the form

$$\begin{aligned}V(X_t, Z_{it}, K_{it}) &= \max_{K_{it+1}} \quad GX_t^{\beta_i} Z_{it} K_{it}^\theta - K_{it+1} + (1 - \delta) K_{it} - \Phi(I_{it}, K_{it}) \\ &\quad + \mathbb{E}_t [M_{t+1} V(X_{t+1}, Z_{it+1}, K_{it+1})]\end{aligned} \quad (31)$$

**Policy function.** The first order and envelope conditions associated with (31) give the Euler equation:

$$\begin{aligned}1 + \xi \left( \frac{K_{it+1}}{K_{it}} - 1 \right) &= \mathbb{E}_t \left[ M_{t+1} \left( G\theta e^{z_{it+1} + \beta_i x_{t+1}} K_{it+1}^{\theta-1} + 1 - \delta - \frac{\xi}{2} \left( \frac{K_{it+2}}{K_{it+1}} - 1 \right)^2 + \xi \left( \frac{K_{it+2}}{K_{it+1}} - 1 \right) \frac{K_{it+2}}{K_{it+1}} \right) \right] \\ &= \mathbb{E}_t \left[ M_{t+1} \left( G\theta e^{z_{it+1} + \beta_i x_{t+1}} K_{it+1}^{\theta-1} + 1 - \delta + \frac{\xi}{2} \left( \frac{K_{it+2}}{K_{it+1}} \right)^2 - \frac{\xi}{2} \right) \right]\end{aligned}$$

In the non-stochastic steady state,

$$\begin{aligned}
MPK &= G\theta K^{\theta-1} = \frac{1}{\rho} + \delta - 1 \Rightarrow K = \left[ \frac{1}{G\theta} \left( \frac{1}{\rho} + \delta - 1 \right) \right]^{\frac{1}{\theta-1}} \\
\Pi &= GK^\theta \Rightarrow D = GK^\theta - \delta K \\
P &= \frac{\rho}{1-\rho} D \\
R &= 1 + \frac{D}{P} = \frac{1}{\rho} \Rightarrow r_f = -\log \rho
\end{aligned}$$

Define the investment return:

$$R_{it+1}^I = \frac{G\theta e^{z_{it+1} + \beta_i x_{t+1}} K_{it+1}^{\theta-1} + 1 - \delta + \frac{\xi}{2} \left( \frac{K_{it+2}}{K_{it+1}} \right)^2 - \frac{\xi}{2}}{1 + \xi \left( \frac{K_{it+1}}{K_{it}} - 1 \right)}$$

and log-linearizing,

$$\begin{aligned}
r_{it+1}^I &= \rho G\theta K^{\theta-1} (z_{it+1} + \beta_i x_{t+1}) + (\rho G\theta (\theta - 1) K^{\theta-1} - \xi (1 + \rho)) k_{it+1} + \rho \xi k_{it+2} + \xi k_{it} \\
&- \log \rho - \rho G\theta (\theta - 1) K^{\theta-1} k
\end{aligned}$$

where  $k = \log K$ .

To derive the investment policy function, conjecture it takes the form

$$k_{it+1} = \phi_{0i} + \phi_1 \beta_i x_t + \phi_2 z_{it} + \phi_3 k_{it}$$

Then,

$$k_{it+2} = \phi_{0i} (1 + \phi_3) + \phi_1 \beta_i (\rho_x + \phi_3) x_t + \phi_2 (\rho_z + \phi_3) z_{it} + \phi_3^2 k_{it} + \phi_1 \beta_i \varepsilon_{t+1} + \phi_2 \varepsilon_{it+1}$$

Substituting into the investment return,

$$\begin{aligned}
r_{it+1}^I &= (\rho G\theta (\theta - 1) K^{\theta-1} - \xi (1 - \rho \phi_3)) \phi_{0i} - \log \rho - \rho G\theta (\theta - 1) K^{\theta-1} k \\
&+ (\rho G\theta K^{\theta-1} \rho_z + (\rho G\theta (\theta - 1) K^{\theta-1} - \xi (1 + \rho)) \phi_2 + \rho \xi (\rho_z + \phi_3) \phi_2) z_{it} \\
&+ (\rho G\theta K^{\theta-1} \rho_x + (\rho G\theta (\theta - 1) K^{\theta-1} - \xi (1 + \rho)) \phi_1 + \rho \xi (\rho_x + \phi_3) \phi_1) \beta_i x_t \\
&+ ((\rho G\theta (\theta - 1) K^{\theta-1} - \xi (1 + \rho)) \phi_3 + \rho \xi \phi_3^2 + \xi) k_{it} \\
&+ (\rho G\theta K^{\theta-1} + \rho \xi \phi_2) \varepsilon_{it+1} + (\rho G\theta K^{\theta-1} + \rho \xi \phi_1) \beta_i \varepsilon_{t+1}
\end{aligned}$$

and

$$\begin{aligned}
r_{it+1}^I + m_{it+1} &= (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 - \rho\phi_3))\phi_{0i} - \rho G\theta(\theta - 1)K^{\theta-1}k - \frac{1}{2}\gamma_0^2\sigma_\varepsilon^2 - \frac{1}{2}\gamma_1^2\sigma_\varepsilon^2x_t^2 \\
&+ (\rho G\theta K^{\theta-1}\rho_z + (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_2 + \rho\xi(\rho_z + \phi_3)\phi_2)z_{it} \\
&+ ((\rho G\theta K^{\theta-1}\rho_x + (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_1 + \rho\xi(\rho_x + \phi_3)\phi_1)\beta_i - \gamma_0\gamma_1\sigma_\varepsilon^2)x_t \\
&+ ((\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_3 + \rho\xi\phi_3^2 + \xi)k_{it} \\
&+ (\rho G\theta K^{\theta-1} + \rho\xi\phi_2)\varepsilon_{it+1} + ((\rho G\theta K^{\theta-1} + \rho\xi\phi_1)\beta_i - \gamma_0 - \gamma_1x_t)\varepsilon_{t+1}
\end{aligned}$$

The Euler equation governing the investment return implies

$$\begin{aligned}
0 &= \mathbb{E}_t[r_{it+1}^I + m_{it+1}] + \frac{1}{2}\text{var}(r_{it+1}^I + m_{it+1}) \\
&= (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 - \rho\phi_3))\phi_{0i} - \rho G\theta(\theta - 1)K^{\theta-1}k \\
&+ (\rho G\theta K^{\theta-1}\rho_z + (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_2 + \rho\xi(\rho_z + \phi_3)\phi_2)z_{it} \\
&+ (\rho G\theta K^{\theta-1}\rho_x + (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_1 + \rho\xi(\rho_x + \phi_3)\phi_1 - (\rho G\theta K^{\theta-1} + \rho\xi\phi_1)\gamma_1\sigma_\varepsilon^2)\beta_i x_t \\
&+ ((\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_3 + \rho\xi\phi_3^2 + \xi)k_{it} \\
&+ \frac{1}{2}(\rho G\theta K^{\theta-1} + \rho\xi\phi_2)^2\sigma_\varepsilon^2 \\
&+ \frac{1}{2}(\rho G\theta K^{\theta-1} + \rho\xi\phi_1)^2\beta_i^2\sigma_\varepsilon^2 - (\rho G\theta K^{\theta-1} + \rho\xi\phi_1)\beta_i\gamma_0\sigma_\varepsilon^2
\end{aligned}$$

and we can solve for the coefficients from:

$$\begin{aligned}
0 &= (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 - \rho\phi_3))\phi_{0i} - \rho G\theta(\theta - 1)K^{\theta-1}k \\
&+ \frac{1}{2}(\rho G\theta K^{\theta-1} + \rho\xi\phi_2)^2\sigma_\varepsilon^2 \\
&+ \frac{1}{2}(\rho G\theta K^{\theta-1} + \rho\xi\phi_1)^2\beta_i^2\sigma_\varepsilon^2 - (\rho G\theta K^{\theta-1} + \rho\xi\phi_1)\beta_i\gamma_0\sigma_\varepsilon^2 \\
&= \rho G\theta K^{\theta-1}\rho_z + (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_2 + \rho\xi(\rho_z + \phi_3)\phi_2 \\
&= \rho G\theta K^{\theta-1}\rho_x + (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_1 + \rho\xi(\rho_x + \phi_3)\phi_1 - (\rho G\theta K^{\theta-1} + \rho\xi\phi_1)\gamma_1\sigma_\varepsilon^2 \\
&= (\rho G\theta(\theta - 1)K^{\theta-1} - \xi(1 + \rho))\phi_3 + \rho\xi\phi_3^2 + \xi
\end{aligned}$$

Define  $\hat{\xi} = \frac{\xi}{\rho G \theta K^{\theta-1}} = \frac{\xi}{1-\rho(1-\delta)}$ . Then,

$$\begin{aligned} 0 &= \left( (\theta - 1) - \hat{\xi} (1 + \rho) \right) \phi_3 + \rho \hat{\xi} \phi_3^2 + \hat{\xi} \\ \phi_1 &= \frac{(\rho_x - \gamma_1 \sigma_\varepsilon^2) \phi_3}{\hat{\xi} (1 - \rho \rho_x \phi_3 + \rho \gamma_1 \sigma_\varepsilon^2 \phi_3)} \\ \phi_2 &= \frac{\rho_z \phi_3}{\hat{\xi} (1 - \rho \rho_z \phi_3)} \\ \phi_{0i} &= \phi_{00} - \phi_{01} \beta_i + \phi_{02} \beta_i^2 \end{aligned}$$

where

$$\begin{aligned} \phi_{00} &= \frac{\rho G \theta (1 - \theta) K^{\theta-1} k + \frac{1}{2} (\rho G \theta K^{\theta-1} + \rho \xi \phi_2)^2 \sigma_\varepsilon^2}{\rho G \theta (1 - \theta) K^{\theta-1} + \xi (1 - \rho \phi_3)} \\ \phi_{01} &= \frac{\phi_3}{\hat{\xi} (1 - \rho \phi_3)} \frac{\gamma_0 \sigma_\varepsilon^2}{1 - \rho \rho_x \phi_3 + \rho \gamma_1 \sigma_\varepsilon^2 \phi_3} \\ \phi_{02} &= \frac{\rho G \theta K^{\theta-1} \rho \xi \phi_1 + \frac{1}{2} (\rho \xi \phi_1)^2 + \frac{1}{2} (\rho G \theta K^{\theta-1})^2}{\rho G \theta (1 - \theta) K^{\theta-1} + \xi (1 - \rho \phi_3)} \sigma_\varepsilon^2 \end{aligned}$$

Note that  $\frac{\phi_3}{\hat{\xi}}$  goes to  $\frac{1}{1-\theta}$  as  $\hat{\xi}$  goes to zero and zero as  $\hat{\xi}$  goes to infinity. Again ignoring variance terms, the policy function is

$$k_{it+1} = \phi_{00} + \phi_1 \beta_i x_t + \phi_2 z_{it} + \phi_3 k_{it} - \phi_{01} \beta_i$$

which is equation (23) in the text.

**MPK Dispersion.** The expected *mpk* is given by

$$\mathbb{E}_t [mpk_{it+1}] = \log \theta + \log G + \beta_i \rho_x x_t + \rho_z z_{it} - (1 - \theta) k_{it+1}$$

and the mean of this is

$$\mathbb{E} [\mathbb{E}_t [mpk_{it+1}]] = \log \theta + \log G - (1 - \theta) \mathbb{E} [k_{it+1}]$$

From the policy function,

$$\mathbb{E} [k_{it+1}] = \frac{\phi_{00} - \phi_{01} \beta_i}{1 - \phi_3}$$

so that

$$\mathbb{E} [\mathbb{E}_t [mpk_{it+1}]] = \log \theta + \log G - \frac{1 - \theta}{1 - \phi_3} (\phi_{00} - \phi_{01} \beta_i)$$

and the variance of this permanent component is

$$\sigma_{\mathbb{E}[\mathbb{E}_t[\text{mpk}_{it+1}]]}^2 = \left( \frac{1-\theta}{1-\phi_3} \right)^2 \phi_{01}^2 \sigma_\beta^2$$

which is equation (24) in the text.

### B.3 Aggregation

The first order condition on labor gives

$$N_{it} = \left( \frac{\theta_2 e^{\hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^{\theta_1}}{W_t} \right)^{\frac{1}{1-\theta_2}}$$

and substituting for the wage,

$$N_{it} = \left( \theta_2 e^{(\hat{\beta}_i - \omega)x_t + \hat{z}_{it}} K_{it}^{\theta_1} \right)^{\frac{1}{1-\theta_2}}$$

Labor market clearing gives:

$$N_t = \int N_{it} di = \theta_2^{\frac{1}{1-\theta_2}} e^{-\frac{1}{1-\theta_2} \omega x_t} \int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^\theta di$$

so that

$$\theta_2^{\frac{\theta_2}{1-\theta_2}} e^{-\frac{\theta_2}{1-\theta_2} \omega x_t} = \left( \frac{N_t}{\int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^\theta di} \right)^{\theta_2}$$

Then,

$$\begin{aligned} Y_{it} &= e^{\hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^{\theta_1} N_{it}^{\theta_2} = \theta_2^{\frac{\theta_2}{1-\theta_2}} e^{-\frac{\theta_2}{1-\theta_2} \omega x_t} e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^\theta \\ &= \frac{e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^\theta}{\left( \int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^\theta di \right)^{\theta_2}} N_t^{\theta_2} \end{aligned}$$

By definition,

$$MPK_{it} = \frac{\theta e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^{\theta-1}}{\left( \int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + \hat{z}_{it}} K_{it}^\theta di \right)^{\theta_2}} N_t^{\theta_2}$$

and rearranging,

$$K_{it} = \left( \frac{\theta e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + z_{it}}}{MPK_{it}} \right)^{\frac{1}{1-\theta}} \left( \frac{N_t}{\int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + z_{it}} K_{it}^\theta di} \right)^{\frac{\theta_2}{1-\theta}}$$

Capital market clearing gives

$$K_t = \int K_{it} di = \theta^{\frac{1}{1-\theta}} \left( \frac{N_t}{\int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + z_{it}} K_{it}^\theta di} \right)^{\frac{\theta_2}{1-\theta}} \int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di$$

so that

$$K_{it}^\theta = \left( \frac{e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}}}{\int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di} K_t \right)^\theta$$

and substituting into the expression for  $Y_{it}$ ,

$$\begin{aligned} Y_{it} &= \frac{e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + z_{it}} \left( \frac{e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}}}{\int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di} K_t \right)^\theta}{\left( \int e^{\frac{1}{1-\theta_2} \hat{\beta}_i x_t + z_{it}} \left( \frac{e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}}}{\int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di} K_t \right)^\theta di \right)^{\theta_2} N_t^{\theta_2}} \\ &= \frac{\frac{e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{\theta}{1-\theta}}}{\left( \int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di \right)^\theta}}{\left( \frac{\int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{\theta}{1-\theta}} di}{\left( \int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di \right)^\theta} \right)^{\theta_2}} K_t^{\theta_1} N_t^{\theta_2}} \end{aligned}$$

Aggregate output is then

$$Y_t = \int Y_{it} di = A_t K_t^{\theta_1} N_t^{\theta_2}$$

where

$$A_t = \left( \frac{\int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{\theta}{1-\theta}} di}{\left( \int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di \right)^\theta} \right)^{1-\theta_2}$$

Taking logs,

$$a_t = (1 - \theta_2) \left( \log \int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{\theta}{1-\theta}} di - \theta \log \int e^{\frac{1}{1-\theta_2} \frac{1}{1-\theta} \hat{\beta}_i x_t + \frac{1}{1-\theta} z_{it}} MPK_{it}^{-\frac{1}{1-\theta}} di \right)$$

The first expression in braces is equal to

$$\begin{aligned} & \frac{1}{1-\theta} \frac{1}{1-\theta_2} \bar{\beta} x_t - \frac{\theta}{1-\theta} \bar{m}pk + \frac{1}{2} \left( \frac{1}{1-\theta} \right)^2 \left( \left( \frac{1}{1-\theta_2} \right)^2 x_t^2 \sigma_{\hat{\beta}}^2 + \sigma_z^2 \right) + \frac{1}{2} \left( \frac{\theta}{1-\theta} \right)^2 \sigma_{mpk}^2 \\ & - \frac{\theta}{(1-\theta)^2} \frac{1}{1-\theta_2} \sigma_{mpk, \hat{\beta}_i x_t + z_{it}} \end{aligned}$$

and the second to

$$\begin{aligned} & \frac{\theta}{1-\theta} \frac{1}{1-\theta_2} \bar{\beta} x_t - \frac{\theta}{1-\theta} \bar{m}pk + \frac{1}{2} \theta \left( \frac{1}{1-\theta} \right)^2 \left( \left( \frac{1}{1-\theta_2} \right)^2 x_t^2 \sigma_{\hat{\beta}}^2 + \sigma_z^2 \right) + \frac{1}{2} \theta \left( \frac{1}{1-\theta} \right)^2 \sigma_{mpk}^2 \\ & - \frac{\theta}{(1-\theta)^2} \frac{1}{1-\theta_2} \sigma_{mpk, \hat{\beta}_i x_t + z_{it}} \end{aligned}$$

and combining (and using  $\sigma_{\beta} = \frac{1}{1-\theta_2} \sigma_{\hat{\beta}}$ ) gives

$$\begin{aligned} a_t &= \bar{\beta} x_t + (1 - \theta_2) \left( \frac{1}{2} \frac{1}{1-\theta} (x_t^2 \sigma_{\hat{\beta}}^2 + \sigma_z^2) - \frac{1}{2} \frac{\theta}{1-\theta} \sigma_{mpk}^2 \right) \\ &= a_t^* - \frac{1}{2} (1 - \theta_2) \frac{\theta}{1-\theta} \sigma_{mpk}^2 \\ &= a_t^* - \frac{1}{2} \frac{\theta_1 (1 - \theta_2)}{1 - \theta_1 - \theta_2} \sigma_{mpk}^2 \end{aligned}$$

## B.4 Stock Market Returns

We derive stock market returns in the environment with adjustment costs. This nests the simpler case without them when  $\xi = 0$ .

Dividends are equal to

$$D_{it+1} = e^{z_{it+1} + \beta_i x_{t+1}} K_{it+1}^{\theta} - K_{it+2} + (1 - \delta) K_{it+1} - \frac{\xi}{2} \left( \frac{K_{it+2}}{K_{it+1}} - 1 \right)^2 K_{it+1}$$

and log-linearizing,

$$d_{it+1} = \frac{\Pi}{D} (z_{it+1} + \beta_i x_{t+1}) + \left( \theta \frac{\Pi}{D} + (1 - \delta) \frac{K}{D} \right) k_{it+1} - \frac{K}{D} k_{it+2} + \log D - \left( \theta \frac{\Pi}{D} - \delta \frac{K}{D} \right) k$$

where  $k = \log K$ . Substituting for  $k_{it+1}$  and  $k_{it+2}$  from Appendix B.2.2 and rearranging,

$$d_{it+1} = A_{0i} + \tilde{A}_1 z_{it} + A_1 \beta_i x_t + \tilde{A}_2 \varepsilon_{it+1} + A_2 \beta_i \varepsilon_{t+1} + A_3 k_{it}$$

where

$$\begin{aligned} A_{0i} &= \log D - \left( \theta \frac{\Pi}{D} - \delta \frac{K}{D} \right) (k - \phi_{0i}) - \frac{K}{D} \phi_{0i} \phi_3 \\ A_1 &= \frac{\Pi}{D} \rho_x + \left( \theta \frac{\Pi}{D} + \frac{K}{D} (1 - \delta - \rho_x - \phi_3) \right) \phi_1 \\ \tilde{A}_1 &= \frac{\Pi}{D} \rho_z + \left( \theta \frac{\Pi}{D} + \frac{K}{D} (1 - \delta - \rho_z - \phi_3) \right) \phi_2 \\ A_2 &= \frac{\Pi}{D} - \frac{K}{D} \phi_1 \\ \tilde{A}_2 &= \frac{\Pi}{D} - \frac{K}{D} \phi_2 \\ A_3 &= \left( \theta \frac{\Pi}{D} + \frac{K}{D} (1 - \delta - \phi_3) \right) \phi_3 \end{aligned}$$

By definition, returns are equal to

$$R_{it+1} = \frac{D_{it+1} + P_{it+1}}{P_{it}}$$

and log-linearizing,

$$r_{it+1} = \rho p_{it+1} + (1 - \rho) d_{it+1} - p_{it} - \log \rho + (1 - \rho) \log \frac{P}{D}$$

Conjecture the stock price takes the form

$$p_{it} = c_{0i} + c_1 \beta_i x_t + c_2 z_{it} + c_3 k_{it}$$

Then,

$$\begin{aligned}
r_{it+1} &= -\log \rho + (1 - \rho) \left( \log \frac{P}{D} + A_{0i} - c_{0i} \right) + \rho c_3 \phi_{0i} \\
&+ \left( (\rho \rho_z - 1) c_2 + \rho c_3 \phi_2 + (1 - \rho) \tilde{A}_1 \right) z_{it} \\
&+ \left( (\rho \rho_x - 1) c_1 + \rho c_3 \phi_1 + (1 - \rho) A_1 \right) \beta_i x_t \\
&+ \left( (\rho \phi_3 - 1) c_3 + (1 - \rho) A_3 \right) k_{it} \\
&+ \left( \rho c_2 + (1 - \rho) \tilde{A}_2 \right) \varepsilon_{it+1} + (\rho c_1 + (1 - \rho) A_2) \beta_i \varepsilon_{t+1}
\end{aligned}$$

and the (log) excess return is the (negative of the) conditional covariance with the SDF:

$$\log \mathbb{E}_t [R_{it+1}^e] = (\rho c_1 + (1 - \rho) A_2) \beta_i \gamma_t \sigma_\varepsilon^2$$

To solve for the coefficients, use the Euler equation. First,

$$\begin{aligned}
r_{it+1} + m_{it+1} &= (1 - \rho) \left( \log \frac{P}{D} + A_{0i} - c_{0i} \right) + \rho c_3 \phi_{0i} - \frac{1}{2} \gamma_0^2 \sigma_\varepsilon^2 \\
&+ \left( (\rho \rho_z - 1) c_2 + \rho c_3 \phi_2 + (1 - \rho) \tilde{A}_1 \right) z_{it} \\
&+ \left( (\rho \rho_x - 1) c_1 + \rho c_3 \phi_1 + (1 - \rho) A_1 \right) \beta_i - \gamma_0 \gamma_1 \sigma_\varepsilon^2 x_t \\
&+ \left( (\rho \phi_3 - 1) c_3 + (1 - \rho) A_3 \right) k_{it} \\
&- \frac{1}{2} \gamma_1^2 \sigma_\varepsilon^2 x_t^2 \\
&+ \left( \rho c_2 + (1 - \rho) \tilde{A}_2 \right) \varepsilon_{it+1} \\
&+ \left( (\rho c_1 + (1 - \rho) A_2) \beta_i - \gamma_0 - \gamma_1 x_t \right) \varepsilon_{t+1}
\end{aligned}$$

The Euler equation implies

$$\begin{aligned}
0 &= \mathbb{E}_t [r_{it+1} + m_{it+1}] + \frac{1}{2} \text{var} (r_{it+1} + m_{it+1}) \\
&= (1 - \rho) \left( \log \frac{P}{D} + A_{0i} - c_{0i} \right) + \rho c_3 \phi_{0i} + \frac{1}{2} (\rho c_1 + (1 - \rho) A_2)^2 \beta_i^2 \sigma_\varepsilon^2 - (\rho c_1 + (1 - \rho) A_2) \beta_i \gamma_0 \sigma_\varepsilon^2 \\
&+ \frac{1}{2} \left( \rho c_2 + (1 - \rho) \tilde{A}_2 \right)^2 \sigma_\varepsilon^2 \\
&+ \left( (\rho \rho_z - 1) c_2 + \rho c_3 \phi_2 + (1 - \rho) \tilde{A}_1 \right) z_{it} \\
&+ \left( (\rho \rho_x - 1) c_1 + \rho c_3 \phi_1 + (1 - \rho) A_1 - (\rho c_1 + (1 - \rho) A_2) \gamma_1 \sigma_\varepsilon^2 \right) \beta_i x_t \\
&+ \left( (\rho \phi_3 - 1) c_3 + (1 - \rho) A_3 \right) k_{it}
\end{aligned}$$

and so by undetermined coefficients,

$$\begin{aligned}
0 &= (1 - \rho) \left( \log \frac{P}{D} + A_{0i} - c_{0i} \right) + \rho c_3 \phi_{0i} + \frac{1}{2} (\rho c_1 + (1 - \rho) A_2)^2 \beta_i^2 \sigma_\varepsilon^2 - (\rho c_1 + (1 - \rho) A_2) \beta_i \gamma_0 \sigma_\varepsilon^2 \\
&+ \frac{1}{2} \left( \rho c_2 + (1 - \rho) \tilde{A}_2 \right)^2 \sigma_\varepsilon^2 \\
&= (\rho \rho_z - 1) c_2 + \rho c_3 \phi_2 + (1 - \rho) \tilde{A}_1 \\
&= (\rho \rho_x - 1) c_1 + \rho c_3 \phi_1 + (1 - \rho) A_1 - (\rho c_1 + (1 - \rho) A_2) \gamma_1 \sigma_\varepsilon^2 \\
&= (\rho \phi_3 - 1) c_3 + (1 - \rho) A_3
\end{aligned}$$

or

$$\begin{aligned}
c_3 &= \frac{(1 - \rho) A_3}{1 - \rho \phi_3} \\
c_2 &= \frac{\rho c_3 \phi_2 + (1 - \rho) \tilde{A}_1}{1 - \rho \rho_z} \\
c_1 &= \frac{\rho c_3 \phi_1 + (1 - \rho) (A_1 - A_2 \gamma_1 \sigma_\varepsilon^2)}{1 - \rho \rho_x + \rho \gamma_1 \sigma_\varepsilon^2}
\end{aligned}$$

Substituting for  $c_1$  we can solve for

$$\log \mathbb{E}_t [R_{it+1}^e] = \frac{\rho^2 c_3 \phi_1 + (1 - \rho) (\rho A_1 + (1 - \rho \rho_x) A_2)}{1 - \rho \rho_x + \rho \sigma_\varepsilon^2 \gamma_1} \beta_i \gamma_t \sigma_\varepsilon^2$$

Solving for

$$\begin{aligned}
\rho A_1 + (1 - \rho \rho_x) A_2 &= \frac{\frac{1}{\rho} + \delta - 1 - \rho \theta \phi_1 \phi_3}{\frac{1}{\rho} + \delta (1 - \theta) - 1} \\
\rho^2 c_3 \phi_1 &= \theta \frac{\rho^2 (1 - \rho) \phi_1 \phi_3}{1 - \rho \phi_3} \frac{\frac{1}{\rho} - \phi_3}{\frac{1}{\rho} + \delta (1 - \theta) - 1}
\end{aligned}$$

substituting into the return equation and simplifying, we obtain

$$\log \mathbb{E}_t [R_{it+1}^e] = \psi \beta_i \gamma_t \sigma_\varepsilon^2$$

where

$$\psi = \frac{\frac{1}{\rho} + \delta - 1}{\frac{1}{\rho} + \delta (1 - \theta) - 1} \frac{1 - \rho}{1 - \rho \rho_x + \rho \gamma_1 \sigma_\varepsilon^2}$$

which is equation (19) in the text.

The Sharpe ratio is the ratio of expected excess returns to the conditional standard deviation of the return:

$$SR_{it} = \frac{\psi\beta_i\gamma_t\sigma_\varepsilon^2}{\sqrt{\left(\rho c_2 + (1-\rho)\tilde{A}_2\right)^2\sigma_\varepsilon^2 + \psi^2\beta_i^2\sigma_\varepsilon^2}}$$

We can solve for

$$\rho c_2 + (1-\rho)\tilde{A}_2 = \frac{\frac{1}{\rho} + \delta - 1}{\frac{1}{\rho} + \delta(1-\theta) - 1} \frac{1-\rho}{1-\rho\rho_z}$$

and substituting and rearranging gives the expression in footnote 37.

For a perfectly diversified portfolio (i.e., the integral over individual returns) idiosyncratic shocks cancel, i.e.,  $\sigma_\varepsilon^2 = 0$  and  $SR_{mt} = \gamma_t\sigma_\varepsilon$ .

## B.5 Autocorrelation of Investment

To derive the autocorrelation of investment, define net investment as  $\Delta k_{it+1} = k_{it+1} - k_{it}$ . We use the following:

$$\begin{aligned} \text{cov}(\Delta z_{it}, z_{it}) &= \text{cov}((\rho_z - 1)z_{it-1} + \varepsilon_{it}, \rho_z z_{it-1} + \varepsilon_{it}) \\ &= \rho_z(\rho_z - 1)\sigma_z^2 + \sigma_\varepsilon^2 \\ &= \frac{1}{1 + \rho_z}\sigma_\varepsilon^2 \\ \text{cov}(\Delta k_{it}, z_{it}) &= \text{cov}(\Delta k_{it}, \rho_z z_{it-1} + \varepsilon_{it}) \\ &= \rho_z \text{cov}(\Delta k_{it}, z_{it-1}) \\ &= \rho_z \text{cov}(\phi_1\beta_i\Delta x_{t-1} + \phi_2\Delta z_{it-1} + \phi_3\Delta k_{it-1}, z_{it-1}) \\ &= \rho_z (\text{cov}(\phi_2\Delta z_{it-1}, z_{it-1}) + \phi_3\text{cov}(\Delta k_{it-1}, z_{it-1})) \\ &= \rho_z\phi_2\frac{1}{1 + \rho_z}\sigma_\varepsilon^2 + \rho_z\phi_3\text{cov}(\Delta k_{it-1}, z_{it-1}) \end{aligned}$$

so that

$$\mathbb{E}[\text{cov}(\Delta k_{it}, z_{it})] = \frac{\rho_z}{1 + \rho_z} \frac{\phi_2\sigma_\varepsilon^2}{1 - \phi_3\rho_z}$$

Next,

$$\begin{aligned} \text{cov}(\Delta k_{it+1}, \Delta z_{it+1}) &= \text{cov}(\phi_1\beta_i\Delta x_t + \phi_2\Delta z_{it} + \phi_3\Delta k_{it}, (\rho_z - 1)z_{it} + \varepsilon_{it+1}) \\ &= \phi_2(\rho_z - 1)\text{cov}(\Delta z_{it}, z_{it}) + \phi_3(\rho_z - 1)\text{cov}(\Delta k_{it}, z_{it}) \\ &= \phi_2(\rho_z - 1)\frac{1}{1 + \rho_z}\sigma_\varepsilon^2 + \frac{\rho_z}{1 + \rho_z} \frac{\phi_3(\rho_z - 1)\phi_2\sigma_\varepsilon^2}{1 - \phi_3\rho_z} \\ &= \frac{\rho_z - 1}{1 + \rho_z} \frac{\phi_2\sigma_\varepsilon^2}{1 - \phi_3\rho_z} \end{aligned}$$

Similar steps give

$$\text{cov}(\Delta k_{it+1}, \Delta x_{t+1}) = \frac{\rho_x - 1}{1 + \rho_x} \frac{\phi_1 \beta_i \sigma_\varepsilon^2}{1 - \phi_3 \rho_x}$$

Combining these gives the variance of investment:

$$\begin{aligned} \sigma_{\Delta k}^2 &= \phi_1^2 \beta_i^2 \text{var}(\Delta x_t) + \phi_2^2 \text{var}(\Delta z_{it}) + \phi_3^2 \sigma_{\Delta k}^2 \\ &+ 2\phi_1 \phi_3 \beta_i \text{cov}(\Delta x_t, \Delta k_{it}) + 2\phi_2 \phi_3 \text{cov}(\Delta z_{it}, \Delta k_{it}) \\ &= \phi_1^2 \beta_i^2 \frac{2}{1 + \rho_x} \sigma_\varepsilon^2 + \phi_2^2 \frac{2}{1 + \rho_z} \sigma_\varepsilon^2 + \phi_3^2 \sigma_{\Delta k}^2 \\ &+ \frac{2\phi_1^2 \phi_3 \beta_i^2 \sigma_\varepsilon^2}{1 - \phi_3 \rho_x} \frac{\rho_x - 1}{1 + \rho_x} + \frac{2\phi_2^2 \phi_3 \sigma_\varepsilon^2}{1 - \phi_3 \rho_z} \frac{\rho_z - 1}{1 + \rho_z} \\ &= \phi_3^2 \sigma_{\Delta k}^2 + 2\phi_1^2 \beta_i^2 \frac{\sigma_\varepsilon^2}{1 + \rho_x} \left(1 + \frac{\phi_3 (\rho_x - 1)}{1 - \phi_3 \rho_x}\right) + 2\phi_2^2 \frac{\sigma_\varepsilon^2}{1 + \rho_z} \left(1 + \frac{\phi_3 (\rho_z - 1)}{1 - \phi_3 \rho_z}\right) \\ &= \frac{2}{1 + \phi_3} \left( \phi_1^2 \beta_i^2 \sigma_\varepsilon^2 \frac{1}{1 + \rho_x} \frac{1}{1 - \phi_3 \rho_x} + \phi_2^2 \sigma_\varepsilon^2 \frac{1}{1 + \rho_z} \frac{1}{1 - \phi_3 \rho_z} \right) \end{aligned}$$

Next,

$$\begin{aligned} \text{cov}(\Delta k_{it+1}, \Delta k_{it}) &= \text{cov}(\phi_1 \beta_i \Delta x_t + \phi_2 \Delta z_{it} + \phi_3 \Delta k_{it}, \Delta k_{it}) \\ &= \phi_1 \beta_i \text{cov}(\Delta x_t, \Delta k_{it}) + \phi_2 \text{cov}(\Delta z_{it}, \Delta k_{it}) + \phi_3 \sigma_{\Delta k}^2 \\ &= \phi_1^2 \beta_i^2 \sigma_\varepsilon^2 \frac{\rho_x - 1}{1 + \rho_x} \frac{1}{1 - \phi_3 \rho_x} + \phi_2^2 \sigma_\varepsilon^2 \frac{\rho_z - 1}{1 + \rho_z} \frac{1}{1 - \phi_3 \rho_z} + \phi_3 \sigma_{\Delta k}^2 \end{aligned}$$

and the autocorrelation is:

$$\text{corr}(\Delta k_{it+1}, \Delta k_{it}) = \phi_3 + \frac{1 + \phi_3}{2} \frac{\phi_1^2 \beta_i^2 \sigma_\varepsilon^2 \frac{\rho_x - 1}{1 + \rho_x} \frac{1}{1 - \phi_3 \rho_x} + \phi_2^2 \sigma_\varepsilon^2 \frac{\rho_z - 1}{1 + \rho_z} \frac{1}{1 - \phi_3 \rho_z}}{\phi_1^2 \beta_i^2 \sigma_\varepsilon^2 \frac{1}{1 + \rho_x} \frac{1}{1 - \phi_3 \rho_x} + \phi_2^2 \sigma_\varepsilon^2 \frac{1}{1 + \rho_z} \frac{1}{1 - \phi_3 \rho_z}} \quad (32)$$

Notice that this approaches

$$\text{corr}(\Delta k_{it+1}, \Delta k_{it}) = \phi_3 + (1 - \phi_3) \frac{\rho_x - 1}{2}$$

as  $\rho_z$  and  $\rho_x$  become close. Further, in the case both shocks follow a random walk, the autocorrelation is simply equal to  $\phi_3$ .

## B.6 Other Distortions

With other distortions, the derivations are similar to those in Appendix B.2.1. The Euler equation is given by

$$\begin{aligned} 1 &= \mathbb{E}_t \left[ M_{t+1} \left( \theta e^{\tau_{it+1} + z_{it+1} + \beta_i x_{t+1}} GK_{it+1}^{\theta-1} + 1 - \delta \right) \right] \\ &= (1 - \delta) \mathbb{E}_t [M_{t+1}] + \theta GK_{it+1}^{\theta-1} \mathbb{E}_t \left[ e^{m_{t+1} + \tau_{it+1} + z_{it+1} + \beta_i x_{t+1}} \right] \end{aligned}$$

**Idiosyncratic distortions.** Substituting for  $m_{t+1}$  and  $\tau_{it+1}$  and rearranging,

$$\begin{aligned} \mathbb{E}_t \left[ e^{m_{t+1} + \tau_{it+1} + z_{it+1} + \beta_i x_{t+1}} \right] &= \mathbb{E}_t \left[ e^{\log \rho - \gamma_t \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2 - \nu z_{it+1} - \eta_{it+1} + z_{it+1} + \beta_i x_{t+1}} \right] \\ &= \mathbb{E}_t \left[ e^{\log \rho + (1-\nu) \rho_z z_{it} + (1-\nu) \varepsilon_{it+1} + \beta_i \rho_x x_t + (\beta_i - \gamma_t) \varepsilon_{t+1} - \frac{1}{2} \gamma_t^2 \sigma_\varepsilon^2 - \eta_{it+1}} \right] \\ &= e^{\log \rho + (1-\nu) \rho_z z_{it} + \beta_i \rho_x x_t + \frac{1}{2} (1-\nu)^2 \sigma_\varepsilon^2 + \frac{1}{2} \beta_i^2 \sigma_\varepsilon^2 - \beta_i \gamma_t \sigma_\varepsilon^2 - \eta_{it+1}} \end{aligned}$$

so that

$$\theta GK_{it+1}^{\theta-1} = \frac{1 - (1 - \delta) \rho}{e^{\log \rho + (1-\nu) \rho_z z_{it} + \beta_i \rho_x x_t + \frac{1}{2} (1-\nu)^2 \sigma_\varepsilon^2 + \frac{1}{2} \beta_i^2 \sigma_\varepsilon^2 - \beta_i \gamma_t \sigma_\varepsilon^2 - \eta_{it+1}}}$$

and rearranging and taking logs,

$$k_{it+1} = \frac{1}{1 - \theta} \left( \tilde{\alpha} + \frac{1}{2} (1 - \nu)^2 \sigma_\varepsilon^2 + \frac{1}{2} \beta_i^2 \sigma_\varepsilon^2 + (1 - \nu) \rho_z z_{it} + \beta_i \rho_x x_t - \beta_i \gamma_t \sigma_\varepsilon^2 - \eta_{it+1} \right)$$

where  $\tilde{\alpha}$  and  $\alpha$  are as defined in Appendix B.2.1.

The realized  $mpk$  is given by (ignoring the variance terms)

$$\begin{aligned} mpk_{it+1} &= \log \theta + \pi_{it+1} - k_{it+1} \\ &= \log \theta + \log G + z_{it+1} + \beta_i x_{t+1} - (1 - \theta) k_{it+1} \\ &= \log \theta + \log G + z_{it+1} + \beta_i x_{t+1} - \tilde{\alpha} - (1 - \nu) \rho_z z_{it} - \beta_i \rho_x x_t + \beta_i \gamma_t \sigma_\varepsilon^2 + \eta_{it+1} \\ &= \alpha + \varepsilon_{it+1} + \beta_i \varepsilon_{t+1} + \nu \rho_z z_{it} + \beta_i \gamma_t \sigma_\varepsilon^2 + \eta_{it+1} \end{aligned}$$

which is equation (26). The conditional expected  $mpk$  is

$$\mathbb{E}_t [mpk_{it+1}] = \alpha + \nu \rho_z z_{it} + \beta_i \gamma_t \sigma_\varepsilon^2 + \eta_{it+1}$$

and the cross-sectional variance is

$$\sigma_{\mathbb{E}_t [mpk_{it+1}]}^2 = (\nu \rho_z)^2 \sigma_z^2 + \sigma_\eta^2 + (\gamma_t \sigma_\varepsilon^2)^2 \sigma_\beta^2 \quad (33)$$

Deriving stock returns follows closely the steps in Appendix B.4. Dividends are equal to

$$D_{it+1} = e^{\tau_{it+1} + z_{it+1} + \beta_i x_{t+1}} K_{it+1}^\theta - K_{it+2} + (1 - \delta) K_{it+1} - \frac{\xi}{2} \left( \frac{K_{it+2}}{K_{it+1}} - 1 \right)^2 K_{it+1}$$

and log-linearizing,

$$d_{it+1} = \frac{\Pi}{D} (\tau_{it+1} + z_{it+1} + \beta_i x_{t+1}) + \left( \theta \frac{\Pi}{D} + (1 - \delta) \frac{K}{D} \right) k_{it+1} - \frac{K}{D} k_{it+2} + \log D - \left( \theta \frac{\Pi}{D} - \delta \frac{K}{D} \right) k$$

where  $k = \log K$ .

Substituting for  $k_{it+1}$  and  $k_{it+2}$  from above,

$$d_{it+1} = A_0 + \tilde{A}_1 z_{it} + A_1 \beta_i x_t + \tilde{A}_2 \varepsilon_{it+1} + A_2 \beta_i \varepsilon_{t+1} + A_3 \eta_{it+1} + A_4 \eta_{it+2}$$

where

$$\begin{aligned} A_0 &= \log D - \left( \theta \frac{\Pi}{D} - \delta \frac{K}{D} \right) \left( k - \frac{\tilde{\alpha}}{1 - \theta} \right) \\ A_1 &= \frac{1}{1 - \theta} \left( \frac{\Pi}{D} + (1 - \delta - \rho_x) \frac{K}{D} \right) \rho_x - \frac{1}{1 - \theta} \left( \theta \frac{\Pi}{D} + (1 - \delta - \rho_x) \frac{K}{D} \right) \gamma_1 \sigma_\varepsilon^2 \\ \tilde{A}_1 &= \frac{1 - \nu}{1 - \theta} \left( \frac{\Pi}{D} + (1 - \delta - \rho_z) \frac{K}{D} \right) \rho_z \\ A_2 &= \frac{\Pi}{D} - \frac{1}{1 - \theta} \frac{K}{D} \rho_x + \frac{1}{1 - \theta} \frac{K}{D} \gamma_1 \sigma_\varepsilon^2 \\ \tilde{A}_2 &= \left( \frac{\Pi}{D} - \frac{1}{1 - \theta} \frac{K}{D} \right) (1 - \nu) \rho_z \\ A_3 &= -\frac{1}{1 - \theta} \left( \theta \frac{\Pi}{D} + (1 - \delta) \frac{K}{D} \right) \\ A_4 &= \frac{1}{1 - \theta} \frac{K}{D} \end{aligned}$$

Using the log-linearized return equation,

$$r_{it+1} = \rho p_{it+1} + (1 - \rho) d_{it+1} - p_{it} - \log \rho + (1 - \rho) \log \frac{P}{D}$$

and conjecturing the stock price takes the form

$$p_{it} = c_0 i + c_1 \beta_i x_t + c_2 z_{it} + c_3 \eta_{it+1}$$

gives

$$\begin{aligned}
r_{it+1} &= -\log \rho + (1 - \rho) \left( \log \frac{P}{D} + A_0 - c_0 \right) \\
&+ \left( (\rho \rho_z - 1) c_2 + (1 - \rho) \tilde{A}_1 \right) z_{it} \\
&+ \left( (\rho \rho_x - 1) c_1 + (1 - \rho) A_1 \right) \beta_i x_t \\
&+ \left( \rho c_2 + (1 - \rho) \tilde{A}_2 \right) \varepsilon_{it+1} + \left( \rho c_1 + (1 - \rho) A_2 \right) \beta_i \varepsilon_{t+1} \\
&+ \left( \rho c_3 + (1 - \rho) A_4 \right) \eta_{it+2} + \left( (1 - \rho) A_3 - c_3 \right) \eta_{it+1}
\end{aligned}$$

The (log) excess return is the (negative of the) conditional covariance with the SDF:

$$\log \mathbb{E}_t [R_{it+1}^e] = (\rho c_1 + (1 - \rho) A_2) \beta_i \gamma_t \sigma_\varepsilon^2$$

$A_2$  is independent of  $\nu$  and  $\eta$ . Following the same steps as in Appendix B.4, it is easily verified that  $c_1$  is independent of these terms as well. Thus, expected returns are independent of distortions.

**Aggregate distortions.** Consider the first formulation, i.e.,

$$\tau_{it+1} = -\nu_z z_{it+1} - \nu_x x_{t+1} - \eta_{it+1}$$

Similar steps as above give expression (33). Dispersion in expected stock market returns are similarly unaffected.

Next, consider the second formulation:

$$\tau_{it+1} = -\nu_z z_{it+1} - \nu_x \beta_i x_{t+1} - \eta_{it+1}$$

In this case, similar steps as above give the conditional expected  $mpk$  as

$$\mathbb{E}_t [mpk_{it+1}] = \alpha + \nu_z \rho_z z_{it} + \nu_x \beta_i \rho_x x_t + (1 - \nu_x) \beta_i \gamma_t \sigma_\varepsilon^2 + \eta_{it+1}$$

and expected excess stock market returns as

$$\log \mathbb{E}_t [R_{it+1}^e] = (1 - \nu_x) \psi \beta_i \gamma_t \sigma_\varepsilon^2$$

where  $\psi$  is as defined in expression (19). In other words, the risk-premium effect on expected  $mpk$ , as well as expected returns, are both scaled by a factor  $1 - \nu_x$ .

The mean level of expected  $mpk$  and return dispersion are, respectively,

$$\begin{aligned}\mathbb{E}\left[\sigma_{\mathbb{E}_t[mpk_{it+1}]}^2\right] &= \sigma_\eta^2 + (\nu_z\rho_z)^2\sigma_z^2 + (\nu_x\rho_x)^2\sigma_x^2\sigma_\beta^2 \\ &\quad + \left((1-\nu_x)\sigma_\varepsilon^2\right)^2(\gamma_0^2 + \gamma_1^2\sigma_x^2)\sigma_\beta^2 + 2\nu_x(1-\nu_x)\rho_x\sigma_x^2\gamma_1\sigma_\varepsilon^2\sigma_\beta^2 \\ \mathbb{E}\left[\sigma_{\log\mathbb{E}_t[R_{it+1}^e]}^2\right] &= \left((1-\nu_x)\psi\sigma_\varepsilon^2\right)^2(\gamma_0^2 + \gamma_1^2\sigma_x^2)\sigma_\beta^2\end{aligned}$$

The last two terms of the first equation capture the  $mpk$  effects of risk premia. The last term there is new and does not have a counterpart in the second equation – in other words, using dispersion in expected returns would give the second to last term, as usual, but not the last. If  $\nu_x < 0$ , it is straightforward to verify that that term is positive (recall that  $\gamma_1$  is negative). Then, we may be understating risk premium effects. If  $\nu_x > 0$ , the last terms is negative and we may be overstating them. At the estimated parameter values, the upper bound on  $\nu_x$  discussed in Section 5.3 is about 0.08. Using this value, along with the other parameters, to calculate the last term in the equation gives the maximum upward bias in our estimates of risk-based dispersion in  $Empk$ , which turns out to be negligible.

## B.7 Multifactor Model

There are  $J$  aggregate risk factors in the economy. Firms have heterogeneous loadings on these factors, so that the profit function (in logs) takes the form

$$\pi_{it} = \beta_i x_t + z_{it} + \theta k_{it} \tag{34}$$

where  $\beta_i$  is a vector of factor loadings of firm  $i$  and  $x_t$  the vector of factor realizations at time  $t$ , i.e.,

$$\beta_i = \begin{bmatrix} \beta_{1i} \\ \beta_{2i} \\ \vdots \\ \beta_{Ji} \end{bmatrix}' \quad x_t = \begin{bmatrix} x_{1t} \\ x_{2t} \\ \vdots \\ x_{Jt} \end{bmatrix}'$$

Each factor, indexed by  $j$ , follows an AR(1) process

$$x_{jt+1} = \rho_j x_{jt} + \varepsilon_{jt+1}, \quad \varepsilon_{jt+1} \sim \mathcal{N}\left(0, \sigma_{\varepsilon_j}^2\right) \tag{35}$$

where the innovations are potentially correlated across factors. Denote by  $\Sigma_f$  the covariance matrix of factor innovations, i.e.,

$$\Sigma_f = \begin{bmatrix} \sigma_{\varepsilon_1}^2 & \sigma_{\varepsilon_1, \varepsilon_2} & \cdots & \sigma_{\varepsilon_1, \varepsilon_J} \\ \sigma_{\varepsilon_2, \varepsilon_1} & \sigma_{\varepsilon_2}^2 & \cdots & \sigma_{\varepsilon_2, \varepsilon_J} \\ \vdots & \vdots & & \vdots \\ \sigma_{\varepsilon_J, \varepsilon_1} & \sigma_{\varepsilon_J, \varepsilon_2} & \cdots & \sigma_{\varepsilon_J}^2 \end{bmatrix}$$

The idiosyncratic component of firm productivity follows

$$z_{it+1} = \rho_z z_{it} + \varepsilon_{it+1}, \quad \varepsilon_{it+1} \sim \mathcal{N}(0, \sigma_{\varepsilon}^2) \quad (36)$$

The stochastic discount factor takes the form

$$m_{t+1} = \log \rho - \gamma \varepsilon_{t+1} - \frac{1}{2} \gamma \Sigma_f \gamma' \quad (37)$$

where  $\gamma$  is a vector of factor exposures and  $\varepsilon_{t+1}$  the vector of innovations in each factor, i.e.,

$$\gamma = \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \vdots \\ \gamma_J \end{bmatrix}' \quad \varepsilon_{t+1} = \begin{bmatrix} \varepsilon_{1t+1} \\ \varepsilon_{2t+1} \\ \vdots \\ \varepsilon_{Jt+1} \end{bmatrix}$$

For simplicity, we have assumed that the factor exposures are constant, although the setup can be extended to include time-varying exposures as well. Expressions (34), (35), (36) and (37) are simple extensions of (9), (7) and (8).

Following a similar derivation as B.2.1, we can derive the realized *mpk*:

$$mpk_{it+1} = \alpha + \varepsilon_{it+1} + \beta_i \varepsilon_{t+1} + \beta_i \Sigma_f \gamma'$$

where  $\beta_i$  and  $\varepsilon_{t+1}$  denote vectors of factor loadings and shocks. The expected *mpk* and its cross-sectional dispersion are given by

$$\mathbb{E}_t [mpk_{it+1}] = \alpha + \beta_i \Sigma_f \gamma', \quad \sigma_{\mathbb{E}_t [mpk]}^2 = \gamma \Sigma_f' \Sigma_{\beta} \Sigma_f \gamma'$$

where  $\Sigma_\beta$  is the covariance matrix of factor loadings across firms, i.e.,

$$\Sigma_\beta = \begin{bmatrix} \sigma_{\beta_1}^2 & \sigma_{\beta_1, \beta_2} & \cdots & \sigma_{\beta_1, \beta_J} \\ \sigma_{\beta_2, \beta_1} & \sigma_{\beta_2}^2 & \cdots & \sigma_{\beta_2, \beta_J} \\ \vdots & \vdots & & \vdots \\ \sigma_{\beta_J, \beta_1} & \sigma_{\beta_J, \beta_2} & \cdots & \sigma_{\beta_J}^2 \end{bmatrix}$$

Similar steps as Appendix B.4 gives

$$\mathbb{E}_t [R_{it+1}^e] = \beta_i \psi \Sigma_f \gamma', \quad \sigma_{\mathbb{E}_t[R]}^2 = \gamma \Sigma_f' \psi' \Sigma_\beta \psi \Sigma_f \gamma'$$

where  $\psi$  is a diagonal matrix with

$$\psi_{jj} = \left( \frac{1 - \rho}{1 - \rho \rho_j} \right) \frac{\frac{1}{\rho} + \delta - 1}{\frac{1}{\rho} + (1 - \theta) \delta - 1}$$

## C Numerical Procedure

Our numerical approach to parameterize the model is as follows. For a given set of the parameters  $\gamma_0$ ,  $\gamma_1$ ,  $\xi$  and  $\sigma_\beta^2$ , we solve the model for a wide grid of beta-types centered around the mean beta. We use an 11 point grid ranging from -3 to 7 (the results are not overly sensitive to the width of the grid). We simulate a time series of excess returns for a large number of firms of each type. We then average the returns across firms in each time period, which yields a series for the market excess return, and compute the mean and standard deviation of this series.

Next we compute the expected return for each beta-type as the mean of the conditional expectation of returns, i.e.,  $\mathbb{E}_t [R_{it+1}] = \mathbb{E}_t \left[ \frac{D_{it+1} + P_{it+1}}{P_{it}} \right]$ . We then use these values to calculate the dispersion in expected returns,  $\sigma_{Er}^2$ , interpolating for values of  $\beta$  that are not on the grid. We use a simulated investment series to calculate the autocorrelation of investment. Finally, we find the set of the four parameters,  $\gamma_0$ ,  $\gamma_1$ ,  $\sigma_\beta^2$  and  $\xi$  that make the simulated moments consistent with the empirical ones, i.e., expected excess market returns, market Sharpe ratio, dispersion in expected returns and autocorrelation of investment. As noted in the text, we implement this procedure for returns using a fourth-order approximation in Dynare++.

## D Additional Portfolio Sorts

This appendix reports additional portfolio sorts and summary statistics by portfolio.

**Portfolio summary statistics.** Table 11 displays summary statistics of firm characteristics across the industry-adjusted MPK-sorted portfolios.<sup>57</sup> A few observations are in order: while size and book-to-market seem to be correlated with firm MPK, the sorting is not monotonic. There are not large differences in the leverage of high and low MPK firms. One possible concern is that our measure of capital omits intangible capital, and that firms that seem to have high MPK (low capital capital utilization) are using intangible capital instead of physical capital. The table shows that this is unlikely to be the case – firms with low MPK, who use capital more intensively, also use intangible capital more intensively, as shown by their relatively high research and development (R&D) expenditures (relative to sales) and also their relatively high sales, general, and administrative (SG&A) expenses (relative to sales), two commonly used measures of investment in intangible capital.

Table 11: Firm Characteristics Across MPK-Sorted Portfolios

<i>Portfolio</i>	Low	2	3	4	High	Pooled
<i>mpk</i>	0.588	1.254	1.572	1.987	2.793	1.639
Market Capitalization	202.8	344.4	355.9	206.2	97.42	241.4
Sales	111.4	333.1	372.2	239.6	104.5	232.2
PPENT	55.31	103.2	87.84	33.25	7.012	57.33
Book Assets	189.6	374.6	385.7	202.3	85.24	247.5
Book to Market Ratio	0.636	0.758	0.765	0.708	0.622	0.698
Profitability	0.069	0.120	0.125	0.123	0.102	0.108
Market Leverage	0.242	0.300	0.307	0.289	0.267	0.281
R&D to Sales Ratio	0.112	0.051	0.044	0.052	0.065	0.064
SGA to Sales Ratio	0.317	0.251	0.239	0.260	0.283	0.270

*Notes:* This table reports the characteristics of firms sorted into five portfolios based on their industry-adjusted *mpk*. Firms are formed into portfolios annually by their (de-meaned by industry-year) *mpk*, for those industry-years with at least 10 firms. We compute the median value for each characteristic for each portfolio in each year, and then average those portfolio medians over time. The stock variables (market capitalization, sales, ppent, book assets) are in millions of 2009 dollars, deflated by the annual CPI. All other variables are ratios. R&D is research and development expenses from Compustat, while SGA is sales, general, and administrative expenses, a measure often associated with intangible capital. Further details on our computation of these measures can be found in appendix A.

**Portfolio sorts - robustness.** Table 12 reports two additional measures of excess returns across portfolios. The first,  $r_{t+3}^e$  computes three year ahead excess returns (compared to one-year ahead in Table 1). The second,  $r_{t+1}^a$  computes one year ahead unlevered returns, which we calculate using an unlimited liability model:  $r_{t+1}^a = \frac{Mktcap}{Mktcap+Debt} r_{t+1}^e$ . The differences in high versus low MPK portfolio returns are robust to these alternatives (for example, the return to

<sup>57</sup>The table displays median firm characteristics, but the means yield qualitatively similar patterns.

the MPK-HML portfolio continues to be both economically and statistically significant, ranging from about 2% to 3.5%).

Table 12: Excess Returns on MPK-Sorted Portfolios – Robustness

<i>Portfolio</i>	Low	2	3	4	High	MPK-HML
Panel A: Not Industry-Adjusted						
$r_{t+3}^e$	9.63*** (2.96)	12.43*** (3.69)	12.69*** (3.71)	13.90*** (3.81)	12.99*** (3.38)	3.36* (1.96)
$r_{t+1}^a$	4.64* (1.88)	7.53*** (3.07)	8.69*** (3.53)	8.66*** (3.26)	8.22*** (3.02)	3.58*** (3.05)
Panel B: Industry-Adjusted						
$r_{t+3}^e$	11.95*** (2.99)	12.27*** (3.71)	12.04*** (3.75)	12.60*** (3.60)	13.82*** (3.58)	1.87** (2.22)
$r_{t+1}^a$	6.86** (2.13)	7.16*** (2.94)	8.04*** (3.37)	8.17*** (3.15)	8.84*** (3.04)	1.97*** (2.66)

*Notes:* This table reports stock market returns for portfolios sorted by *mpk*.  $r_{t+3}^e$  denotes equal-weighted annualized monthly excess stock returns (over the risk-free rate) measured from July of year  $t + 3$  to June of year  $t + 4$ .  $r_{t+1}^a$  denotes equal-weighted unlevered (“asset”) returns from from July of year  $t + 1$  to June of year  $t + 2$ , where we use an unlimited liability model to unlever equity returns. Industry adjustment is done by demeaning *mpk* by industry-year and sorting portfolios on de-meaned *mpk*, where industries are defined at the 4-digit SIC code level. *t*-statistics in parentheses, computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$

Table 13 reports the results of the portfolio sorts across 10, rather than 5, portfolios. We report contemporaneous returns,  $r_t^e$ , one year ahead returns,  $r_{t+1}^e$ , three year ahead returns,  $r_{t+3}^e$  and one year ahead unlevered returns,  $r_{t+1}^a$ . Across these various alternatives, there are significant differences between low and high MPK portfolios. The MPK-HML spread ranges from over 3.5% for unlevered within-industry returns to almost 11% for contemporaneous returns.

Next, Table 14 reports the results of portfolio sorts after controlling for firm size and book-to-market. To control for size, we allocate in each industry-year (so all sorts are industry-adjusted) by market capitalization. We then demean each firm’s *mpk* by the mean of their industry-year-size group and sort firms into five portfolios based on this measure. We report the results in the top panel of Table 14. The table shows that even when controlling for size, high MPK firms tend to offer higher expected returns than low ones. We follow a similar procedure to control for book-to-market and report the results in the bottom panel of the table. Again, the spreads in expected returns remain after controlling for this variable.

As a second approach to controlling for these variables, Tables 15 and 16 display the results from double-sorting on MPK and size and book-to-market, respectively. To ensure that there are a sufficient number of firms in each portfolio, we use three portfolios along each dimension. The portfolios are ranked from low to high MPK along the columns and from small to large

Table 13: Excess Returns on MPK-Sorted Decile Portfolios

<i>Portfolio</i>	Low	2	3	4	5	6	7	8	9	High	MPK-HML

*Notes:* This table reports stock market returns for portfolios sorted by *mpk*.  $r_t^e$  denotes equal-weighted contemporaneous annualized monthly excess stock returns (over the risk-free rate) measured in the year of the portfolio formation from January to December of year  $t$ .  $r_{t+1}^e$  denotes the analogous future returns, measured from July of year  $t+1$  to June of year  $t+2$ .  $r_{t+3}^e$  denotes future returns further in the future, measured as returns from July of year  $t+3$  to June of year  $t+4$ .  $r_{t+1}^a$  denotes equal-weighted unlevered (“asset”) returns from from July of year  $t+1$  to June of year  $t+2$ , where we use an unlimited liability model to unlever equity returns. Industry adjustment is done by de-meaning *mpk* by industry-year and sorting portfolios on de-meaned *mpk*, where industries are defined at the 4-digit SIC code level.  $t$ -statistics in parentheses, computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$

along the rows. We calculate the MPK-HML spread as well as the small-minus-big spread (the size premium). The left-hand panel reports unconditional expected returns and the right-hand panel after adjusting for industry. Reading across the rows, the table shows that within each size bin, high MPK firms tend to offer higher expected returns than low ones (although the spread is not always statistically significant, which may be a function of (a) either a small number of firms in some of the portfolios or (b) the fact that size and MPK tend to be correlated, e.g., Table 11). Table 16 reports analogous results using book-to-market, along with the high-minus-low spread (the value premium). Our findings are similar – high MPK firms offer higher expected returns than low ones. The MPK-HML spread is positive within each book-to-market bin and is generally large and statistically significant.

Table 14: Excess Returns on MPK-Sorted Portfolios Controlling for Size and Book-to-Market

<i>Portfolio</i>	Low	2	3	4	High	MPK-HML
Panel A: Industry and Market Cap Adjusted						
$r_{t+1}^e$	12.18*** (2.60)	12.51*** (3.29)	12.95*** (3.67)	13.61*** (3.56)	14.70*** (3.40)	2.52** (2.12)
Panel B: Industry and Book-to-Market Adjusted						
$r_{t+1}^e$	9.55** (2.03)	10.44*** (2.83)	11.03*** (3.11)	12.77*** (3.37)	13.24*** (3.04)	3.70*** (2.60)

*Notes:* This table reports stock market returns for portfolios sorted by *mpk*. Panel A contains *mpk*-sorted future excess returns after de-meaning by firms of similar market capitalization within the same industry. We split firms in each year-industry into three groups based on their market capitalization and then construct *mpk* residuals by subtracting the mean *mpk* of the industry-year-size group from firm *mpk*. We then sort firms into five portfolios based on their residuals. In Panel B we construct the analogue of this procedure using book-to-market ratios instead of market capitalization. We define an industry at the 4-digit SIC code level. We compute equal-weighted forward annualized monthly excess stock returns (over the risk-free rate), measured in the year following the portfolio formation, from July of year  $t+1$  to June of year  $t+2$ .  $t$ -statistics in parentheses, computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$

Table 15: Excess Returns on MPK and Size Portfolios

*Notes:* This table reports stock market returns for portfolios, double sorted by *mpk* and book-to-market ratios. We measure equal-weighted forward annualized monthly excess stock returns (over the risk-free rate), measured in the year following the portfolio formation, from July of year  $t + 1$  to June of year  $t + 2$ .  $t$ -statistics in parentheses, computed using Newey-West standard errors. Significance levels are denoted by: \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$
