BECKER MEETS KYLE: INSIDE INSIDER TRADING

Marcin Kacperczyk and Emiliano Pagnotta

This Discussion Paper is issued under the auspices of the Centre's research programme in **FINANCIAL ECONOMICS**. Any opinions expressed here are those of the author(s) and not those of the Centre for Economic Policy Research. Research disseminated by CEPR may include views on policy, but the Centre itself takes no institutional policy positions.

The Centre for Economic Policy Research was established in 1983 as an educational charity, to promote independent analysis and public discussion of open economies and the relations among them. It is pluralist and non-partisan, bringing economic research to bear on the analysis of medium- and long-run policy questions.

These Discussion Papers often represent preliminary or incomplete work, circulated to encourage discussion and comment. Citation and use of such a paper should take account of its provisional character.

BECKER MEETS KYLE: INSIDE INSIDER TRADING

Abstract

How do illegal insiders trade on private information? Do they internalize legal risk? Using hand-collected data on insiders prosecuted by the SEC, we find that, consistent with Kyle (1985), insiders manage trade size and timing according to market conditions and the value of information. Gender, age, and profession play a lesser role. Various shocks to penalties and likelihood of prosecution show that insiders internalize legal risk by moderating aggressiveness, providing support to regulators' deterrence ability. Consistent with Becker (1968), following positive shocks to expected penalties, insiders concentrate on fewer signals of higher value. Thus, enforcement actions could hamper price informativeness.

Becker Meets Kyle: Inside Insider Trading[*]

Marcin Kacperczyk[†]   Emiliano S. Pagnotta[‡]

Abstract

How do illegal insiders trade on private information? Do they internalize legal risk? Using hand-collected data on insiders prosecuted by the SEC, we find that, consistent with Kyle (1985), insiders manage trade size and timing according to market conditions and the value of information. Gender, age, and profession play a lesser role. Various shocks to penalties and likelihood of prosecution show that insiders internalize legal risk by moderating aggressiveness, providing support to regulators' deterrence ability. Consistent with Becker (1968), following positive shocks to expected penalties, insiders concentrate on fewer signals of higher value. Thus, enforcement actions could hamper price informativeness.

First Draft: March 16, 2018. ***This Version***: August 6, 2019

A large literature in economics and finance argues that private information is transmitted into asset prices through the actions of informed traders. The canonical representation of this process is given by the Kyle model (1985): knowing the fundamental value of an asset, and internalizing the price impact of trades, an informed trader cautiously spreads trades over time. However, the literature largely abstracts from *how* the private information is produced. In the Grossman–Stiglitz (1980) tradition, a trader pays a fee to become informed, usually regarded as the cost of fundamental research. In real markets, however, private information can be also obtained by an insider in breach of a fiduciary duty, generating exposure to legal risks and converting a regular investor into a criminal. Do such *illegal* informed traders behave rationally, as in the Kyle model? Do they internalize legal risks, as in Becker (1968)? Our understanding of these questions is important, since it has implications for efficiency and welfare (Ausubel (1990); Fishman and Hagerty (1992); Leland (1992)) and capital formation (Manove (1989); Easley and O'Hara (2004)). Moreover, it could help regulators to better understand the potential deterrence effect of insider trading laws and enhance detection infrastructure (DeMarzo et al. (1998)). While important, these questions pose formidable identification challenges: neither private information nor legal risks are observable.

To address these challenges, we collect data on illegal trading investigations prosecuted by the U.S. Securities and Exchange Commission (SEC) that documents in detail how certain individuals trade on nonpublic information and summarizes the legal outcomes. We characterize over 5,000 trades in 840 firms from 1995 to 2015, representing a fairly large universe of assets and market conditions. In the first part of the paper, we examine in depth the information sets, trading strategies, and penalties of illegal insider traders, a study that, to our knowledge, has never been undertaken. We provide direct evidence on their trading horizons, the value distribution of their private signals, and the dynamics of information transmission and construct several metrics of strategic behavior, including the degree of order splitting and measures of informed trade size. To better understand the determinants of those strategies, we develop and test a simple Kyle framework of informed trading activity in which we incorporate legal penalties and random deadlines. Finally,

to evaluate the influence of enforcement actions on strategies, we design multiple quasi-natural experiments that exploit exogenous sources of variation in legal risk. To sum up, controlling for individual-level behavioral predictors, the evidence provides strong support both to the predictions of the Kyle-like framework and to the notion that legal risk influences trading strategies.

Sections 1 and 2 provide an end-to-end characterization of illegal insider trading, from the moment in which a private tip on the fundamentals of a given firm is received to the resolution of the legal penalties. First, we assess the value of the information motivating trades by computing hypothetical stock returns that one could realize by initiating a trade when receiving the tip and closing the trade immediately after the corresponding public announcement. The average return of 32.29% indicates that such value is economically large, especially since it accrues over a relatively short period, with a mean information horizon of 28 days. Earnings and merger and acquisition (M&A) events, the two dominant categories, display significantly different averages: 17.78% and 44.26%. On average, M&A events involve smaller firms, with more short-run upside potential. These figures do not account for embedded leverage in options, which represent 31.83% of the trades in the sample. The distribution of profits is highly skewed: the average and median profits per trader are $757,127 and $44,318. The counterpart of such profitability is found in the value of penalties: the mean and median pecuniary penalties are $2.85 million and $0.2 million. Slightly more than 10% of the traders are sentenced to jail.

The empirical characterization of the trading strategies offers several novel perspectives. First, consistent with the Kyle model, most traders split trades over time, albeit to different degrees. Among these, the median trader splits trades over a period equivalent to 71% of the information horizon. At the same time, we find that about 20% of insiders do not split their trades at all. Also consistent is the finding that splitting occurs not only over time but also in quantities. Conditional on trading at multiple dates, a simple measure of volume duration indicates that quantities are fairly evenly distributed over time. Finally, we document a great degree of skewness in the distribution of total dollar volume, with average and median trades of $1.56 million and $0.15 million. The distribution of volume is heterogeneous across assets: on days when insiders trade, they represent

nearly 10% of the total volume for stocks and 30% for options.

In the second part of the paper, we aim to understand insiders' trading decisions. Section 3 develops a benchmark two-period Kyle model in which insiders decide when and how much to trade. Apart from an adverse realization of uninformed traders' order flow, we incorporate two additional sources of risk that are more pertinent to our research setting. Traders face legal risk associated with possible enforcement action, with penalties that are proportional to the economic value of the trade, and they face information risk, that is, the possibility that the information will become public after only one period. The latter risk is likely to affect trades motivated by unscheduled announcements (e.g., Back and Baruch (2004)), but also reflects the risk of competition more broadly (e.g., Holden and Subrahmanyam (1992)). Insiders face a crucial tradeoff: to trade more aggressively when facing greater information risk, or to act more conservatively—splitting orders more evenly and reducing trade size—when facing higher expected legal costs. The equilibrium outcome is a response to the relative strengths of these two forces.

Alternatively, traders' actions could reflect limited rationality, as supported by ample research in psychology, sociology, and economics.[1] A first possibility, the *legal overconfidence hypothesis*, is that illegal insiders act as in the traditional Kyle model, but neglect legal risk. This is because they may be overconfident in their ability to avoid legal punishment. Indeed, evidence from the crime literature (Piliavin et al. (1986)) suggests that individuals tend to underestimate legal risk when committing crime. Notably, overconfidence is more common for males (Barber and Odean (2001)) or individuals with high social status (Deaux and Farris (1977)), both being overly represented in our data. A second possibility, the *limited skill hypothesis*, is that, although mindful of legal consequences, individuals do not fully internalize risks related to the trading environment, such as liquidity or information risks. This could be because they lack investment skills. Indeed, our sample contains individuals who work in the finance industry or have top executive jobs (e.g., hedge fund traders at the Galleon Group and SAC Capital Advisors), but also those who have backgrounds seemingly unrelated to trading, such as medical doctors and lawyers.[2]

---

[1] Bazerman and Moore (2009) summarize the literature in a general business context. Barberis and Thaler (2003) provide a summary of the literature from the financial economics perspective.

[2] Arguably, a less plausible case is one in which insiders exhibit reckless behavior, ignoring all associated risks,

In Section 4, we construct empirical counterparts for the benchmark model parameters. We associate events with high information risk to unscheduled M&A events, and validate this intuitive approach by showing that the time between receiving the private tip and the initiation of trades is shorter for these. To proxy for legal risk at the trader level, we use predictive regressions where the dependent variable indicates the legal outcome, either pecuniary or jail penalties. We use controls that are predetermined relative to trades, representing as best as possible traders' ex ante information sets. Interestingly, the penalties are strongly related to the traders' legal residence, which uniquely determines the litigation court. On the other hand, we find that penalties do not relate significantly to a host of variables that are likely to affect trading decisions.

To test our hypotheses on insiders' strategies, we exploit a regression design that includes as controls the information and legal risk measures, as well as proxies for the Kyle model parameters and several individual-level characteristics (age, gender, professional background). Among many valuable insights, we find that, first, the baseline predictions from the Kyle model on strategies hold: the value of information and the volatility of the asset value and uninformed trading play an important role. Second, insiders internalize legal risk. Everything else being constant, traders facing higher legal risk tend to split their trades more and place orders of more moderate size. Third, traders also factor in information risk: consistent with the theory, cases with high information risk display values of trade splitting that are, on average, 18% lower, and display relatively lower volume duration. All the results are qualitatively similar when we estimate our empirical models using instrumental variables (IV) method implemented via 2SLS, with 77 court assignments as instruments, and Post-LASSO estimation that is meant to reduce the noise in the instruments. In sum, we do not find support for the legal overconfidence hypothesis. Arguably, the finding that 20% of traders do not split their orders does not allow us to completely rule out the limited skill hypothesis.[3] Finally, we do not find evidence that, relative to the model parameters, personal

legal or otherwise.

[3]We do not interpret the presence of these traders as a direct violation of the Kyle model, since it could be optimal for some of these traders not to split orders over multiple dates. For example, high idiosyncratic information risk could induce such a response. At best, that proportion provides an upper bound on the limits of rationality. More likely, this finding suggests that additional frictions, such as attention allocation or other fixed costs, could be important. Consistent with this intuition, investors who do not split their trades trade smaller quantities, so they could be relatively less concerned about price impact.

characteristics are equally important: virtually all the coefficients of these controls are statistically insignificant. Overall, relative to the benchmark, traders display a remarkable degree of rationality.

A potential identification concern regarding the impact of legal risk is that omitted variables that influence predicted penalties could also affect trades. Such concern is alleviated by the lack of systematic relation between penalties and the various predictors of strategic decisions that we consider, and evidence from the IV estimation. Nonetheless, in the interest of robust identification, we design multiple quasi-natural experiments that exploit plausibly exogenous sources of variation in legal risk. We consider three such time-series tests in Section 5, and three cross-sectional ones in Section 6. The underlying hypothesis is common across tests: if legal risk increases (decreases), insiders should act more (less) prudently. The model gives content to the notion of prudence: the insider should trade lower quantities and exhibit relatively more early volume and order splitting.

In the first time-series test, we argue that the adoption of the *Dodd–Frank Act* strengthened legal risk. Indeed, we document that, in the wake of the new regulation, related federal penalties increased significantly. We then show that, as a result of this change, the average insider shifts trade volume to earlier periods and is less likely to submit large trades. Our second time-series shock is the 2014 Supreme Court ruling on the *United States v. Newman*, which significantly narrowed the application of insider trading laws, and was subsequently used as a precedent to redeem many allegedly guilty subjects. We find that, following this shock, the average trader becomes *less* cautious, increasing quantities and trading duration. Finally, we investigate whether *subjective* perceptions of risk can influence strategies. With that goal, we design a test that exploits Google Trends searches associated with the phrase *illegal insider trading*. Our results indicate that periods of high incidence of such searches are associated with more prudent insider behavior.

We further take advantage of the cross-sectional variation in legal risk. Specifically, we investigate the impact of Preet Bharara, the U.S. Attorney of the Southern District of New York (SDNY), who earned the reputation of a "crusader" prosecutor. Given that his employment spell was ex ante uncertain, we regard his 2009–2013 tenure as a positive shock to legal risk. We find that traders *within* the SDNY jurisdiction significantly reduced their trade aggressiveness over this period. In

5

another test, we exploit differences in detection sources: we contrast the trades of insiders who are detected through the SEC whistleblower reward program (WRP) with those identified through different means. We argue that traders in the WRP group are likely to be more sophisticated, since regulatory agencies, by design, fail to identify their trades; therefore, their sensitivity to legal shocks could be different. We find that WRP traders reduce quantities more sharply in response to the Dodd–Frank Act enforcement shock. Finally, we consider the trades of investors who, according to the SEC, traded on superior information, but, according to a judge, acted *lawfully*. We show that their strategies show *more aggressive* trading profiles, consistent with them not acting under the threat of similar legal risk.

Besides the various tests on strategies, we also assess the impact of legal risk from the perspective of the ex ante choice of engaging in criminal activity. Following the insights from Becker (1968), a rational trader who internalizes legal risk would be less willing to act on any given private signal if either the probability of enforcement or the conditional penalty increases. Under this view, the result of a shock to expected legal costs is that the insider acts on fewer private signals with higher expected returns. We test this hypothesis by comparing the average private signal value motivating trades before and after the time-series shocks to legal risk considered before. Consistent with this canonical crime model, we identify a strong increase in that average during times of greater risk.

Our paper relates to several strands of literature. First, we contribute directly to the literature on illegal insider trading. In addition to the theoretical work on illegal insider trading, on the empirical front, an important paper by Meulbroek (1992) documents its impact on stock returns and market efficiency. Our evidence on the importance of expected legal costs suggests that the institutional framework is an important determinant of market efficiency. More recently, Del Guercio et al. (2017) study the effect of a time-varying enforcement environment on price discovery. Their evidence is consistent with our time-series characterization of expected legal risk. Kallunki et al. (2018) analyze the impact of wealth on the decision to engage in insider trading. We complement their results by providing evidence on the impact of expected legal costs. Also related are the studies of Cornell and Sirri (1992) on stock liquidity and Kacperczyk and Pagnotta (2019) on asymmetric information

6

proxies. Ahern (2017) analyzes insider traders' networks and their relation to information spread and individual profits. While these studies also use insider trading investigations in some capacity, they do not investigate the relation between the trading strategies of insiders and legal risks, which is our most significant contribution.

Second, we provide new theoretical and empirical evidence on what determines the use of private information in financial markets. Theoretical literature has identified links between private information and stock liquidity (e.g., Glosten and Milgrom, 1985; Kyle, 1985; Easley and Hara, 1987), option liquidity (e.g., Biais and Hillion, 1994), stock price volatility (e.g., Wang, 1993), and option price volatility (e.g., Back, 1993). Relative to the literature, we embed the legal considerations in the Kyle-type equilibrium and show the tradeoffs between information and liquidity vs. enforcement. Empirically, Cohen et al. (2012) and Klein et al. (2017), among others, examine the characteristics of legal trades by corporate insiders. Among the few empirical studies that have carefully examined flows of private information in financial markets are those of Koudijs (2015, 2016). Our evidence in support of Kyle model predictions on *strategies* complements that of Koudijs, which is based on stock return correlations from the 18th-century Amsterdam market. We note that the historical setting in the latter study precedes currently prevailing insider trading laws. We also extend this setting to include both information and legal risk in a direct empirical testing.

Finally, also related is a large literature that empirically analyzes financial misconduct.[4] Among others, Dyck et al. (2010) analyze the behavior of whistleblowers in the context of corporate fraud. Karpoff and Lou (2010) discuss the importance of short sellers for the detection of financial report misrepresentations. Kedia and Rajgopal (2011) study the role of constraints in the SEC budget for committing fraud by corporate managers. Egan et al. (2018) analyze a sample of financial advisers and analyze ex post penalties imposed on such advisers. Our paper is, to the best of our knowledge, the first to focus on the ex ante implications of legal risk, for both trading behavior and private information transmission.

---

[4]For a comprehensive perspective on the economics of crime, see Freeman (1999).

1 Insider Trading and Legal Penalties: Data Collection and Summary Statistics

To gain the broadest possible perspective on insider trading investigations, we retrieve a list of all SEC litigation press releases containing the term insider trading. We use this list to obtain all the available civil complaint files available on the SEC website. In cases in which the complaint file is not available, we rely on information from the U.S. District Court where the case is filed and/or manual web searches. In the Internet Appendix A, we provide background on legal aspects of insider trading prosecution and illustrate the main elements of an insider trading case by considering the case of Matthew Martoma, one of the most prominently featured insiders over the last few decades.

1.1 Insiders' Trades and Profile

We collect all files starting from January 2001 until December 2015.[5] The resulting sample of 453 legal cases represents all SEC cases describing insider trading activity spanning trades between 1995 and 2015 that were either litigated or settled out of court. The average number of investigations per year in our sample is 30.83, with a maximum number of cases (46) filed in 2012. Similar to the case of Martoma, most complaint files include a detailed account of the allegations, including biographical records of the defendants, individual trades, a description of the associated corporate event, and the relationships between the tippers and tippees.

The information is organized by characterizing trades and information events. A *trade* is any single transaction record for which we can observe a date and a trading instrument (e.g., stocks or options). For most trades, additional information about the price, trade direction, quantity, trading profits, and the closing date of the position is also available. An *information event* is a collection of one or more trades that were motivated by a unique piece of private information, such as an earnings announcement or a merger. The key information event records include the companies involved, the

---

[5]We track all documents that provide updates on a previously released complaint file. Whenever updated information is available at a later date, we rely on the most recent version. Kacperczyk and Pagnotta (2019) use these files to study the relation between the presence of informed traders and the behavior of empirical proxies of asymmetric information.

nature of the leaked information, and the date at which the information was released to the public.

Firms and trades. The data collection yields a total of 5,058 unique trades involving 840 firms. The top panel of Table I displays general characteristics of the sample of trades and associated firms. The distribution of the number of firms per case is highly asymmetric. While the mean is slightly over two, approximately 80% of the cases involve a single firm, while 4% of the cases involve 10 firms or more. The sample is fairly evenly distributed over time, with over 100 trades in each year between 1999 and 2014. The observed dispersion of trades across years is an attractive feature, since it allows us to address identification issues related to time-specific macro events. The majority of cases involve single trades in a given company, but the mean and median trader in the sample executes close to 20 and 10 trades, respectively, with a maximum of 97 trades. The median firm generates 13 trades.

Corporate events, industries, and traded assets. Table II describes the event types, trading instruments, and affected firms. The most frequent event categories are M&As (55.90%), followed by earnings announcements (15.06%). The business events and corporate events categories (10.71%) include, among others, items such as information about products, a firm's projects, patents, Food and Drug Administration medical trials, corporate restructuring, bankruptcy, and fraud. Given the importance of M&As in our sample, the majority of private signals are positive. Across all events, there are 4,220 buys (83.43%) and 838 sells. The vast majority of trades are executed via stocks (67.06%) and options (31.83%). The remaining few are trades in American depositary shares and bonds. The three most represented industry sectors in our sample are chemicals, business services, and electronic equipment, which account for more than 40% of all trades. However, we note that the trading involves companies spanning almost all industrial sectors.

Personal and professional background. Table A1 in the Internet Appendix summarizes the available personal background for the 1,079 traders in the sample. The median ages of the tippers and traders are almost identical and equal 45 years and 46 years, respectively. The vast majority of tippers and traders are male. Specific corporate roles are available for 410 traders, and we observe

a substantial cross-sectional dispersion among these. Low- and mid-level management positions account for 25.61% and 20.48% of traders, respectively. Top corporate positions, defined as vice president rank or higher, amount to 53.90% of jobs. An important number of traders work in the finance industry, including 59 portfolio managers, 30 brokers/dealers, and 21 analysts. Among those individuals with non-finance jobs, the top four occupations involve business owners, lawyers, medical doctors, and accountants.

Profits. The goal of any insider trading scheme is to generate monetary profits. In most investigations, the SEC reports the profits that are generated by the traders involved. We also collect this information to understand its distribution. The average trade profit is $757,127 and the median profit is $44,318. About 49% of trades elicit at least $100,000 in profits. The most profitable trade within our sample is that of Martoma.

1.2 Legal Penalties

Legal risk can materialize through two types of penalties: pecuniary ones, typically determined in the process of civil court investigation, and non-pecuniary ones, determined through a criminal investigation. Typically, monetary penalties are set in proportion to the trading profits. Criminal cases usually end up with two types of resolutions: a jail penalty or probation. The jail penalty varies from as little as a few months to several years. Probation does not usually last longer than three years. In civil courts, occasionally, a case presented by the SEC can be dismissed due to lack of strong evidence. Anecdotally, these are usually politically popular cases, or cases with a significant amount of insider trading (e.g., Steve Cohen of SAC Capital).

We collect detailed information on each type of penalty for each defendant in the sample. Some of the information is reported in the complaint files reported by the SEC. However, a significant fraction of the files is missing the relevant information. We append information to such missing records through website searches that include court reports, newspaper articles, and legal websites (e.g., LexisNexis). We obtain precise dollar figures for 587 traders. Panel B of Table I summarizes the data. The average monetary penalty for a given trader in our sample amounts to $2.85 million,

Figure 1. Insiders' trade values and monetary penalties
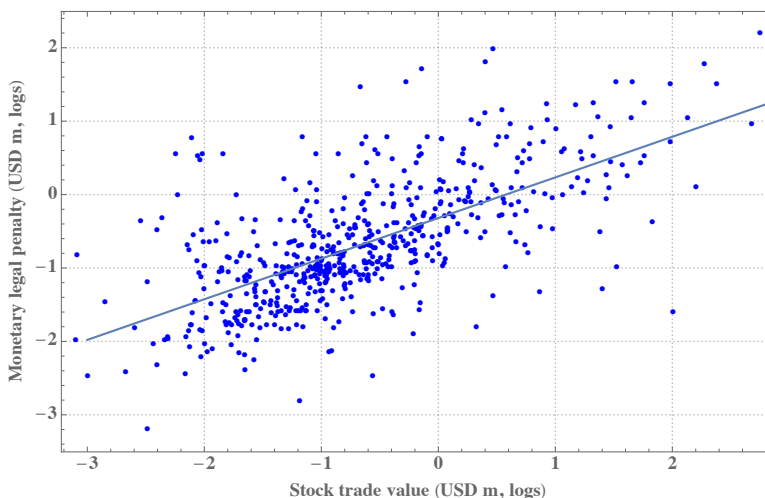

while the median is \$0.2 million. The largest individual penalty corresponds to Raj Rajaratnam of Galleon Group and equals approximately \$160 million. The average total penalty per case, that is, including all involved trades, equals \$11.74 million, with a median of \$1.25 million. Penalties can vary across traders in a given case. The average standard deviation of within-case penalties equals \$3.16 million, though the median is significantly smaller and equal to \$0.08 million. More than 10% of traders in our sample receive a jail penalty, with an average duration of 3.5 years. In a given case, 10% of traders are jailed. An additional 23.5% of traders receive probation. Finally, 12% of traders have their cases dropped.

The assignment of cases to courts is generally based on the geographic proximity to the trader's permanent address. We collect details on the different courts involved, since, in principle, the severity of the penalties could depend on the ruling court. The sample includes a total of 77 different courts. The most prominently featured courts include the SDNY (30.4% of cases), the District of Columbia (6.1%), and the Central District of California (5.5%).

Penalties and trades. In most situations, penalties take the form of a monetary sum determined by a court's decision or as the outcome of an out-of-court settlement with the SEC. Although penalties are frequently determined in relation to profits, a significant proportion of the profit figures

Figure 2. Time line of an insider trading case
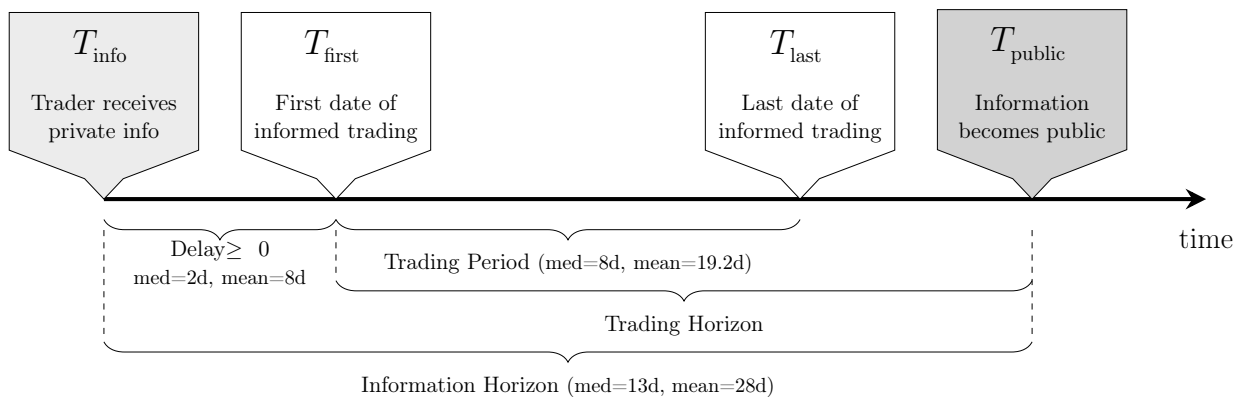

reported in the investigations are joint figures involving multiple traders. To gain perspective on the relation between penalties and the economic magnitude of the insider trading scheme, however, we can relate individual penalties to individual trades, since the latter are available in most cases. The result is displayed in Figure 1 using a logarithmic scale. Interestingly, although the relation between trade value and penalties is certainly not deterministic, one can observe a strong and positive association between these two variables. The relation documented here implies that trade values can be seen as a reasonable proxy for expected penalties. We exploit this insight in later sections.

2 Private Signals and Insiders' Strategies: Direct Evidence from SEC Investigations

In this section, we document novel facts about the duration of such information episodes, the value of private signals, and the relation between information transmission and trades. Moreover, we exploit precisely identified insider trading dates and quantities to construct measures of strategic behavior that summarize the actual use of private information.

2.1 Information and Trade Horizons

We begin with characterizing the most important dates in a given investigation, which we graphically present in Figure 2. The event begins on date T_{info}, when the trader receives a private signal about a given firm's fundamentals. Such an information advantage disappears on date T_{public} when that private information becomes public (e.g., a quarterly earnings release date). Given $\{T_{\text{info}}, T_{\text{public}}\}$, the trader decides upon $\{T_{\text{first}}, T_{\text{last}}\}$, the first and last dates of trading. Because trades are motivated by private information, $T_{\text{first}} \geq T_{\text{info}}$ and $T_{\text{last}} \leq T_{\text{public}}$. We take both T_{info} and T_{public} as exogenous parameters from the trader's perspective, while trading days can be better seen as endogenous. This allows us to benchmark individual investors' trading decisions. Accordingly, we define the *information horizon* as $T_{\text{public}} - T_{\text{info}}$ and the *trading horizon* as $T_{\text{last}} - T_{\text{first}}$, both measured as the number of days. The trading horizon is trivially exogenous in the limit case in which $T_{\text{info}} = T_{\text{public}}$, that is, when the trader receives the signal just before the public announcement.

The left panel of Figure 3 displays the distribution of information horizons for the entire sample. The mean and median values are 13 days and 28 days. The center and right panels display the distributions for earnings and M&A events, respectively. Private information is longer lived for M&A events: the mean value of 32 days is more than twice the value for earnings, which is 12.4 days. Given the unscheduled nature of M&A announcements, some of which are delayed for months, we observe significantly greater skewness in the right tail of the distribution. We also note that the median delay between the arrival and the use of information is two days, and that the median period from any given trade until T_{public} is seven days. The median trading horizon is eight days.

2.2 The Value of Private Signals

The SEC verifies the material and nonpublic nature of information in insider trading investigations. But how material is the information received? In other words, how strong is its information content? To shed light on this aspect, we exploit an attractive feature of our sample: the ability to observe when information is received by traders. Accordingly, for each information event, we compute the percentage change in the corresponding stock price from the opening price on date T_{info} to the

13

Figure 3. Distribution of private information horizons

This figure displays the distribution of private information horizons ($T_{\text{public}} - T_{\text{info}}$). The left panel corresponds to all the events. The center and right panels correspond to earnings and M&A events, respectively.
opening price immediately after the information becomes public, on date $T_{\text{public}} + 1$. We denote the absolute value of such a return as the *private signal value* (PSV):

$$PSV := \left| \frac{\text{Opening Price}(T_{\text{public}} + 1) - \text{Opening Price}(T_{\text{info}})}{\text{Opening Price}(T_{\text{info}})} \right|. \tag{1}$$

The left panel of Figure 4 displays the distribution of PSV for the entire sample. The mean and median values are remarkably high, at 45.97% and 32.29%, respectively. The center and right panels show that the distributions for earnings and M&A events are quite different: the median PSV value for earnings is only 17.78%, while the median value for M&A events is 44.36%. Indeed, for a non-negligible fraction of M&A cases, the value of PSV is greater than 100%. These PSV values are remarkably large, especially in light of the median information horizon of two weeks. Moreover, one could treat these returns as a lower bound on actual profitability, since about 30% of trades are in options, hence embedding leverage.

2.3   Characterizing Insider Trading Strategies

Once a trader is in possession of private information, a trader must design a strategy. In principle, a strategy is a complex contingent plan involving times, quantities, and prices. It is difficult to empirically summarize all of these different dimensions using a single metric. Therefore, we construct four simple measures reflecting specific aspects, and refer to them as *strategic decisions.*

14

Figure 4. Distribution of private signal values

This figure displays the distribution of *PSV* (see equation (1)). The left panel corresponds to all the events. The center and right panels correspond to earnings and M&A events, respectively.
We consider two measures that reflect the timing of informed trades. First, given that strategic informed traders are expected to distribute their trades over multiple periods, we exploit precisely identified trade dates to define *Splitting* as the ratio between the trading and information horizons:

$$Splitting := \frac{T_{\text{last}} - T_{\text{first}}}{T_{\text{public}} - T_{\text{info}}} \subseteq [0, 1]. \tag{2}$$

To illustrate the application of *Splitting*, consider Martoma's trade in ELN and WYE, as described in the Internet Appendix A. The information horizon is 12 days ($T_{\text{info}} = 07/17/08$ and $T_{\text{public}} = 07/29/08$). The trading horizon is eight days ($T_{\text{first}} = 07/21/08$ and $T_{\text{last}} = 07/29/08$). Therefore, *Splitting* = ²/₃.

Second, to account for the time distribution of trades *within* the trading horizon, we define *Duration* as follows:

$$Duration := \frac{1 \times |\text{Informed vol}_{\text{early}}| + 2 \times |\text{Informed vol}_{\text{late}}|}{|\text{Informed vol}_{\text{early}}| + |\text{Informed vol}_{\text{late}}|} \subseteq [1, 2], \tag{3}$$

where Informed vol$_{\text{early}}$ and Informed vol$_{\text{late}}$ are the dollar values of informed trades during the first and second half of the trading horizon, respectively. In contrast to *Splitting*, *Duration* reflects how early trades are executed rather than whether they are spread out over time. Intuitively, values of *Duration* close to two indicate that a high proportion of the informed trade volume is executed near

T_{public}.[6] Because $Informedvol$ is based on dollar figures, we restrict the computation of $Duration$ to stock trades. For options, approximating the dollar value is challenging, because a significant proportion of option trades in the investigations do not contain all the contract characteristics (i.e., either exact moneyness or maturity is missing).

Next, we use precisely identified trade quantities to define two volume-related measures. First, $Bet :=$ Informed vol, is the total dollar value that an insider trades over the entire trading horizon. Second, $Intensity$ is the ratio of informed trading relative to the normal market volume, defined as the average daily dollar volume for the same asset over the previous calendar year. Formally, for any given trader, we compute

$$Bet := \text{Informed vol (over } [T_{\text{first}}, T_{\text{last}}]), \tag{4}$$

$$Intensity := \max_{a} \left\{ \frac{\text{Informed vol}_a}{\text{Normalvol}_a} \right\}, \tag{5}$$

where $a \in \{$stocks, calls, puts$\}$. The max operator reflects the fact that some traders, such as Martoma, use both stocks and options. For options, the normal volume is computed across all contracts with the same underlying stock.

Next, we characterize the distributions of the strategic decisions. For $Splitting$, we first show that, perhaps surprisingly, the proportion of cases in which insiders do not split their trades is economically significant. Indeed, the proportion of cases in which investors trade only on one day equals 20.8% for trades motivated by earnings and 18.8% for those motivated by M&A events. The proportion of single-day trades is higher in the case of stocks, at 23.4%, than for options, at 14.6%.[7] The variable $Duration$ for these trades is trivially equal to one.

Second, for the majority of cases in which some degree of order splitting is observed, we observe a substantial amount of cross-sectional heterogeneity, as shown in the top left panel of Figure 5.

---

[6]Although alternative definitions of order splitting could be conceived, unlike in our analytical framework, for many investigations the exact informed volume for each date within the trading horizon is not available. The four dates in the calculation of $Splitting$, on the other hand, are available in virtually all investigations. Hence, we believe that simultaneously considering $Splitting$ and $Duration$ is particularly important to better understand timing aspects.

[7]We note that, albeit limited, some degree of order splitting is still possible in a single day. We face data limitations in reflecting such intraday splitting, since we do not observe intraday time stamps.

Figure 5. Distributions of strategic decisions

This figure displays, from top to bottom, the empirical distribution of *Splitting*, *Duration*, *Bet*, and *Intensity* (see equations (2) to (5)). The distributions of *Splitting* and *Duration* are conditional on nonzero values.
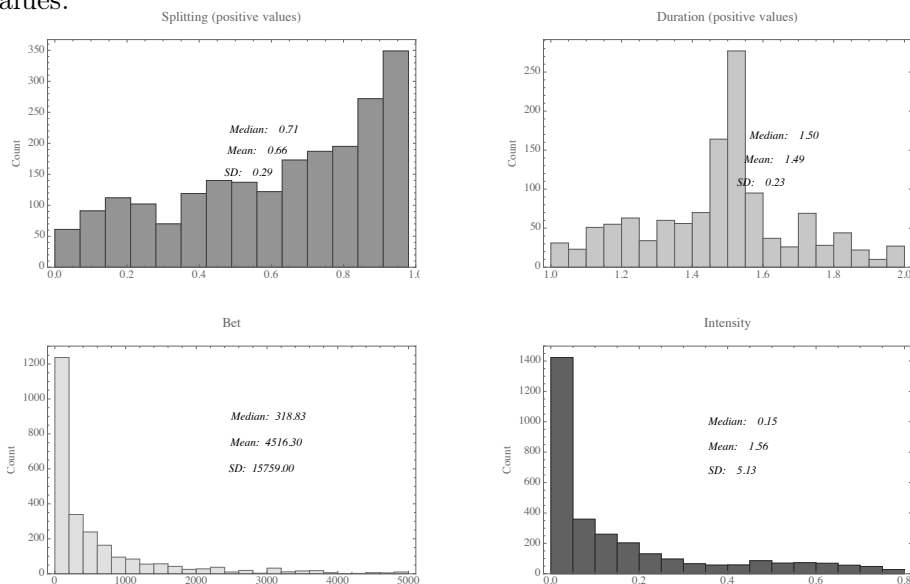

Notably, the median value is relatively high, at 0.71, indicating that traders take advantage of a significant proportion of the private information horizon. The top right panel shows that the distribution of *Duration* is remarkably symmetric for cases with more than one trade: the median value equals exactly 1.5. This finding suggests that the median trader splits orders *both* across times and quantities. As for *Splitting*, we also observe a wide range of cross-sectional attitudes for this strategic dimension.

The bottom panels show the distributions of *Bet* and *Intensity*, both of which are highly skewed. The median value of *Intensity* is 7%, while the mean is more than twice that amount, 19%. Moreover, we observe significant heterogeneity across trading instruments. On average, when insiders are present, 10.76% of the corresponding daily stock volume can be attributed to their trades; for options, that proportion is 34.27%.

3 A Simple Analytical Framework

In this section, we analyze a simple theoretical framework that allows us to benchmark insiders' strategic decisions. Following the seminal contributions of Kyle (1985) and Becker (1968), we consider a profit-driven rational informed trader who internalizes both liquidity and legal risks. The insider also faces the risk of information loss, that is, the risk of losing his/her information advantage before the public announcement of the private signal. Such information risk stylistically captures the fact that a large proportion of the information sets have uncertain announcement dates, including M&As and the results of medical trials or patents.

3.1 Information and the Enforcement Environment

We consider a two-period strategic trading model in the tradition of Kyle (1985). The value of the asset v satisfies $v \sim N(p_0, \sigma_v^2)$. One informed trader observes v at time 0 and submits market orders x_t, $t = 1, 2$. Nonstrategic liquidity traders submit market orders of size u_t, with $u_t \sim N(0, \sigma_u^2)$. A competitive market maker observes the aggregate order flow given by $y_t = x_t + u_t$ and sets the asset price p_t accordingly.

Apart from an adverse realization of uninformed orders u, the informed trader faces two additional sources of risk. The first one is *information risk*. With probability ρ, the value v is publicly announced between periods 1 and 2 and the informed trader loses his/her informational advantage after one period. Everything else being equal, unscheduled corporate announcements can be linked to high values of ρ. In contrast, scheduled corporate earnings can be seen as events with relatively low ρ values.[8]

Second, the informed trader internalizes *legal risk*. The regulatory agency detects the illegal trade with probability q and, in that case, assigns a monetary penalty C. The expected penalty, K, is thus $q \times C$. We assume that enforcement takes place after trades, that is, any legal penalty

---

[8]We note that ρ can still be positive for earnings, for example, if quarterly figures accidentally leak to the public in advance of the announcement. Moreover, the insider can be concerned that other insiders could receive the same tip and become competitors (e.g., Holden and Subrahmanyam (1992)). To keep the analysis simple, we interpret greater risk of competition as an increase in the same parameter, ρ. Extensions of the Kyle model with uncertain horizons have been previously considered by Back and Baruch (2004), Caldentey and Stacchetti (2010), and Koudijs (2015), among others.

is known after period 2. Furthermore, conditional on detection, the penalty is set according to $C(x_1, x_2) = c(|x_1| + |x_2|)^2$, $c > 0$. One can interpret insider trading detection as originating from a whistleblower or industry player, such as a broker reporting suspicious trades to a regulator, either x_1 or x_2 or both. Regardless of the detection method, analysis of the insider's trading account by regulators reveals the sequence $\{x_1, x_2\}$.[9] The fact that C is an increasing function of x reflects the intuitive fact that the regulator imposes penalties that are proportional to the economic importance of the illegal trade. The quadratic functional form is primarily chosen for tractability.[10] Although the evidence in Section 1.2 suggests that monetary penalties might not bear a convex relation with trade size, such a relation could be reasonable, provided that large illegal trades are more likely to lead not only to civil prosecution but also to criminal prosecution. In other words, potential jail penalties for large trades (and a greater loss of reputation) can be seen as having large pecuniary equivalents.

We note that information risk and legal risk are likely to imply different trade paths. If information is lost after period 1, one would not anticipate $x_2 > 0$. Otherwise, regardless of the ex-post investigation outcome, the insider is likely to trade in each period. In other words, the regulator can impose ex-post penalties on insider trading, but cannot stop trades in either period.

---

[9]Assuming that q is entirely unrelated to x and/or u is not without loss of generality. Endogenizing q is quite challenging within the Kyle model as it makes a market maker's learning process very complex. Moreover, regulators do not make their data-based detection methods public, which makes such an exercise highly speculative. DeMarzo et al. (1998) study a model in which the probability of insiders' detection is correlated with total trading volume. To the best of our knowledge, their approach does not lead to an analytical solution in a dynamic Kyle setting. For a given nondecreasing C function, however, it is reasonable to expect that introducing a detection function satisfying $q'(y_t) > 0$ would intensify the incentive to split orders evenly.

[10]We note that the case with a penalty function that is linear in the trades of the insider requires a numerical solution, since the strategy of the insider is nonlinear in the private signal v. Such a numerical approach would make the characterization of the equilibrium less transparent, without necessarily bringing different insights regarding the negative relation between expected penalties and trade aggressiveness. Carre et al. (2018) also assume an exogenous detection probability and provide an analytical solution to a one-period Kyle-like model with linear penalties, but adopting a uniform distribution for the model's random variables instead of the traditional normal case. While interesting, their approach is not directly applicable to this setting since we are interested in multiperiod trading.

3.2 Trade Dynamics and Equilibrium

At the beginning of period 1, having observed v, the informed trader has a value function V_1 given by

$$V_1 = \max_{x_1 \in \mathbb{R}} \left\{ \mathbb{E} \left[(v - p_1) x_1 + (1 - \rho) V_2 | v \right] - \rho K (x_1) \right\}. \tag{6}$$

The third term in equation (6) corresponds to the expected penalty in the event that information is disclosed early and trading in period 2 becomes worthless, where $K (x_1) = q \times c x_1^2$.

Conditional on no early disclosure, the value function in period 2 is given by

$$V_2 = \max_{x_2 \in \mathbb{R}} \left\{ \mathbb{E} \left[(v - p_2) x_2 | v, p_1 \right] - K (x_1, x_2) \right\}. \tag{7}$$

Competition and informational efficiency force the market maker to set prices $p_1 = p_0 + \mathbb{E} \left[v - p_0 | y_1 \right]$ and $p_2 = p_1 + \mathbb{E} \left[v - p_1 | y_1, y_2 \right]$. The following proposition characterizes the resulting linear equilibrium.

Proposition 1. *There exists a unique linear equilibrium with* $x_t = \alpha_t + \beta_t v$ *and* $p_t = p_{t-1} + \lambda_t (x_t + u_t)$, $t = 1, 2$, *given by*

$$\beta_1 = \frac{\left(1 - \left(\frac{1-\rho}{2\gamma_2} \right) (\lambda_1 + 2qc) \right)}{2 \left(\gamma_1 - (\lambda_1 + 2qc)^2 \left(\frac{1-\rho}{4\gamma_2} \right) \right)}, \quad \alpha_1 = -p_0 \beta_1, \tag{8}$$

$$\beta_2 = \frac{1}{2\gamma_2} (1 - 2qc\beta_1), \quad \alpha_2 = \frac{1}{2\gamma_2} (2qc\beta_1 p_0 - p_1), \tag{9}$$

$$\lambda_1 = \frac{\beta_1 \sigma_v^2}{\beta_1^2 \sigma_v^2 + \sigma_u^2}, \tag{10}$$

$$\lambda_2 = \frac{\beta_2 \sigma_v^2}{\left(\beta_2^2 + \beta_1^2 \right) \sigma_v^2 + \sigma_u^2}, \tag{11}$$

$$\gamma_t = (\lambda_t + qc). \tag{12}$$

Proposition 1 allows us to investigate the connections between the information and legal variables, and the behavior of insiders and market makers, $\{ \beta_t, \lambda_t : t = 1, 2 \}$. These relations are illus-

trated in Figure B2 of the Internet Appendix. Next, we exploit such connections to derive empirical predictions for order timing and trade quantities.

3.3 Empirical Predictions

To illustrate the implications of the model's equilibrium, we study the average trading behavior of the informed trader using metrics that resemble the (italicized) strategic statistics in Section 2:

$$\text{Splitting} = \mathbb{E}\left(1 - \frac{|x_1 - x_2|}{|x_1| + |x_2|}\right), \tag{13}$$

$$\text{Duration} = \mathbb{E}\left(\frac{1 \times |x_1| + 2 \times |x_2|}{|x_1| + |x_2|}\right), \tag{14}$$

$$\text{Intensity} = \mathbb{E}\left(\frac{|x_1| + |x_2|}{2}\right). \tag{15}$$

The variable *Splitting* in (13) reflects how evenly distributed informed trades are over time, and takes a value equal to zero if all the trades are concentrated in a single period, and a value equal to one if all the trades are identical. The variable *Duration* reflects the proportion of early/late trade volume, taking on a value between one and two. The variable *Intensity* captures the average informed trade volume. Because there is only one asset in the framework, the expression is simpler than its empirical counterpart of equation (5).

We simulate trading sessions to compute the moments defined by equations (13) to (15). The median information horizon in the sample equals two weeks and, therefore, in assigning parameter values, we interpret a period as representing a trading week. We set the standard deviation of noise trading equal to the within-sample standard deviation of the stock volume at weekly frequencies, $\sigma_u = 67.49$. To set σ_v, we consider a representative stock price of $p_0 = 10$ and find the standard deviation value that rationalizes the mean PSV value in the sample. We do so by inverting the mean equation of the folded normal distribution,[11] obtaining $\sigma_v = 8.43$. For expositional clarity, in the simulations that follow, we condition the moments on paths for which there is no early information disclosure.

---

[11]Recall that, if $x \sim N(\mu, \sigma)$, $y = |x|$ has a mean value $\mu_Y = \sigma\sqrt{\frac{2}{\pi}}e^{\left(-\mu^2/2\sigma^2\right)} + \mu\left(1 - 2\Phi\left(\frac{-\mu}{\sigma}\right)\right)$.

Figure 6. Empirical predictions: Legal risk
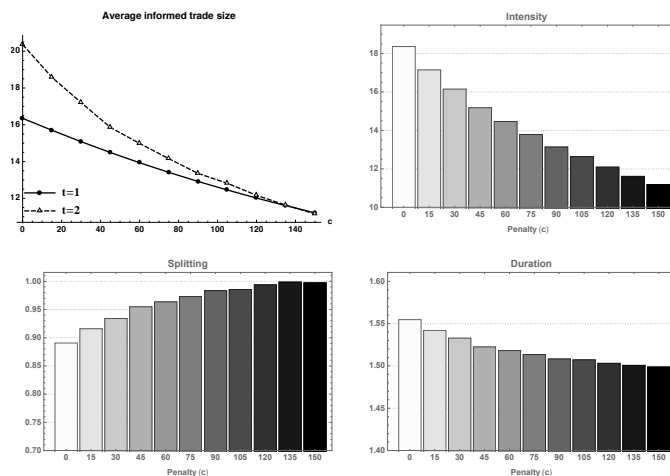

Legal risk. To develop economic intuition, consider first the case in which the insider faces legal risk but no information risk ($c > 0$, $\rho = 0$). The top left panel of Figure 6 displays the average informed trade size per period, and the remaining panels display the strategic metrics (13) to (15). As the penalty parameter c increases, the insider internalizes expected enforcement costs by reducing the order size in each period and, in equilibrium, the price is less informative of the private signal. Note, however, that the effects on trade sizes are not identical. Indeed, penalties act as a factor that increases the effective impact of an informed trade, thereby incentivizing more even trades over time, thus increasing the value of *Splitting*. As the relative weight of trades at time $t = 1$ increases, the value of *Duration* decreases.

Information risk. Consider now the case in which the insider faces information risk but no risk of legal penalty ($\rho > 0$, $c = 0$). The left panel of Figure 7 displays the average informed trade size, and the remaining panels display the strategic metrics (13) to (15). As the risk of losing the information advantage increases, the insider trades more aggressively in the early trading round and less aggressively in the late one. These trading patterns imply that the value of *Splitting* increases for relatively low values of ρ, and decreases for relatively high values. The effect on *Duration*, on

22

Figure 7. Empirical predictions: Information risk
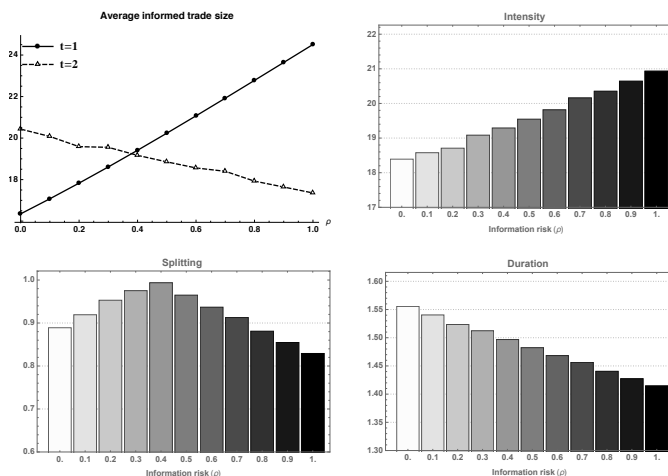

the other hand, is monotonic: the greater the value of ρ, the greater the importance of informed trading in the first period. In the aggregate, the informed trade volume increases and *Intensity* displays higher values.

Kyle model parameters. Besides legal and information risk, the economic environment is defined by three primitives that are also present in the traditional Kyle model: the value of private signal realization, $(v - p_0)$, the volatility of noise trading, σ_u; and the ex-ante volatility of asset value, σ_v. We briefly comment on the impact of parameter changes, as illustrated in Figure B3 of the Internet Appendix. As one would expect, an increase in the value of the private signal increases the average trade size in each period and, therefore, increases *Intensity*. On the other hand, *Splitting* and *Duration* are unaffected, since the relation between β_1 and β_2 is not driven by the realization of v. Also familiar is the effect of an increase in σ_u and σ_v, which have a positive and a negative effect on *Intensity*, respectively. The effect on *Splitting* is also of the opposite sign: an increase in σ_u decreases its value while an increase in σ_v induces the informed trader to split trades more evenly.

Next, based on the insider trading and legal penalties samples in Section 1, we construct empirical proxies of the various parameters and design empirical tests to evaluate the model's predictions.

23

4 Empirical Strategy and Baseline Results

We are interested in understanding the determination of insider traders' strategic trading decisions in light of the economic fundamentals discussed in previous sections. For that, we estimate the following regression model:

$$StrategicDecision_i = a + b \times Kyle_i + c \times Indiv_i + d \times Inforisk_i + e \times Legalrisk_i + \text{error}_i, \quad (16)$$

where *StrategicDecision* refers to either *Splitting, Duration, Bet,* or *Intensity,* as defined in Section 2.3. The vector of variables *Kyle* in equation (16) corresponds to a set of controls that act as proxies for the parameters of the model in Section 4. To proxy for the asset value uncertainty (σ_v), we use *Realized Volatility,* based on 30-minute stock returns and averaged over the previous calendar year. We measure the amount of noise trading (σ_u) using the average volatility of the daily trading volume over the previous calendar year, *Volume Vol.* To account for the value of the private signal, we compute *Strength* by replacing T_{info} by T_{first} in equation (1). This is because movements in the market price can cause the value of the private signal at the time of trading to differ from the corresponding PSV. We also include the natural logarithm of market capitalization, *Ln (mkt. cap),* to account for the ex-ante heterogeneity in liquidity levels that can affect informed traders' decisions. Table III provides descriptive statistics for the dependent variables and regressors.

Next, we elaborate on the specification of additional control variables related to individual characteristics and the measures of information risk and legal risk.

4.1 Individual Characteristics

Prior behavioral research shows that trading behavior could be affected by individual characteristics such as age, gender, or occupation. For example, age could proxy for individual risk aversion. Holding everything else constant, one could expect older traders to behave more conservatively. On the other hand, age could be a proxy for career concerns, implying that older insider traders could exhibit greater risk tolerance. Similarly, various psychological studies argue that males are,

on average, more overconfident than females. As such, they should be less sensitive to penalties and other risks. Finally, trading expertise could affect the propensity to place trades carefully, for example, by splitting trades more extensively.

To account for the above characteristics, we add the following additional controls: *Age,* corresponding to traders' age (in years); *Gender,* an indicator variable equal to one if a trader is a male, and zero if the trader is a female (note that the traders in our sample are predominantly male and, therefore, we could have limited statistical power to identify gender effects); *Executive,* is an indicator variable that equals one when the trader is a top executive in any industry (ranked as vice president or higher); and *Finance* is an indicator variable that equals one when the trader works in the financial services industry. The latter two variables can be seen as proxies for trading experience or familiarity with the trading process of stocks and options; each one encompasses about a fourth of the individuals in the sample.

An additional individual-specific factor we consider relates to the information source, as follows. We define *Tipper Insider* as an indicator variable that equals one if the trader or tipper works for the affected company. The intuition we rely on is that traders could deem information as being more reliable when its source comes directly from the affected firm (first-hand information). High information precision could reduce the incentive to wait for subsequent signals, decreasing *Duration*, and/or could induce larger trade sizes.

4.2   Information Risk

To proxy for information risk, that is, the risk that private information is lost before T_{public}, we primarily rely on the content of the information sets. Specifically, we define an indicator variable *Inforisk* as equal to one for trades associated with M&A activity, and zero for all other trades. The intuition is that, relative to alternative corporate events such as earnings announcements, M&A events expose the insider trader to a higher risk of an early public announcement.

Second, as an alternative way to measure information risk, we consider the number of traders involved in a given SEC investigation, *NumberTraders*. Economic intuition suggests that the speed

of information use should increase when there is a threat of losing it to a competitor (e.g., Holden and Subrahmanyam, 1992). In this context, however, the connection between the number of informed traders and information risk is more nuanced, because those traders could be part of an insider trading ring. Nonetheless, we hypothesize that the larger the number of individuals who have access to the private signal, the larger the risk that such a signal is lost to a potential competitor. Hence, traders acting on information that has also been disseminated to others could be less willing to delay action.

To assess whether our empirical proxies are related to actual information risk, we explore whether they affect the opportunity cost of delaying informed trading, measured as the interval between receiving the private signal, T_{info}, and T_{first}. Formally, we define *ActionDelay* as

$$ActionDelay := \frac{T_{\text{first}} - T_{\text{info}}}{T_{\text{public}} - T_{\text{info}}} \subseteq [0, 1].$$

If the type of corporate announcement or the number of traders is related to information risk, one would expect to see a negative relation with *ActionDelay*. To assess such a hypothesis, we estimate the following regression model:

$$ActionDelay_i = a + b \times Inforisk_i + c \times Traders_i + d \times Controls_i + error_i,$$

where *Controls* is a vector of control variables including those in *Kyle* and *Individual* as in equation (16). Table IV presents the estimation results. Column (1) corresponds to a univariate regression model without controls. Columns (2) and (3) extend the empirical specification by adding *Kyle* and *Indiv* as controls, respectively. We obtain very similar results in all specifications: there is a strong and inverse relation between *ActionDelay* and *Inforisk*, consistent with the above intuition. The coefficient is both statistically and economically significant. In the most comprehensive model, moving from scheduled events to unscheduled events reduces *ActionDelay* by 33% of the variable's cross-sectional standard deviation. At the same time, *NumberTraders* does not display a significant statistical association. Therefore, in the subsequent section, we rely on *Inforisk* as a primary

empirical proxy for information risk.

A discussion of the direction of the two additional estimated coefficients is also noteworthy. We observe a negative and statistically significant coefficient for *Strength*, indicating that traders use their private signals more quickly when they are more valuable. Such an effect is consistent with the notion of heterogeneous opportunity costs of delaying trades in the context of an uncertain information horizon. On the other hand, insiders delay the use of private signals relatively more when trading stocks with high *Realized Volatility*, which seems intuitively consistent with the value of the option to delay action.

4.3   Legal Risk

In the analysis of Section 3, the informed trader internalizes the effect of the expected penalty cost as given by the product between the probability of legal enforcement and the conditional penalty. Ideally, one would like to account for each variable separately in the cross-sectional analysis. Theoretically, say, the probability of detection could vary from one trader or financial institution to another. However, such an approach is clearly infeasible. Instead, we rely here on the random assignment of insider traders to courts as a source of exogenous variation in expected penalty, and explore probability shocks to probabilities in subsequent sections. The courts are staffed by judges and prosecutors who differ in their propensity to penalize insiders. As a result, which court a defendant is assigned to influences whether he/she will be penalized and how much.[12]

The idea of random assignment of traders to courts is predicated by the rule that the court assignment is solely determined by the physical address of the trader. To the extent that the traders cannot easily manipulate their address the assignment of traders to courts is conditionally random. We further test this idea by estimating the following equation:

$$Y_i = \alpha + \beta \times Court_i + error_i,$$

---

[12]This identification strategy has been used in numerous applications where judges, case workers, or other types of program administrators are given discretion on how to respond to a randomly assigned cases (e.g., Mueller-Smith (2015)).

where Y is an insider trader characteristic in $Indiv$, and $Court$ is a vector of indicator variables for court assignment. To evaluate if the observed caseloads are statistically equivalent, we conduct an F-test of the joint significance of the coefficients in β. We repeat this procedure with sentencing outcomes to establish a baseline of the instrument relevance based on average court differences. Table C2 of the Internet Appendix shows the results of this exercise. The first part of the panel shows the F-tests for differences in the balance of defendant covariates: *Age, Gender, Executive,* and *Finance.* The second panel shows the F-tests for differences in the balance of sentencing outcomes. The test statistics for insider characteristics range between 1.47 and 2.03. These indicate a technical rejection of the null hypothesis but capture very minor differences in court balance. In contrast, the test statistics for sentencing outcomes are significantly greater, 25.46 for pecuniary penalties and 7.77 for jail penalties, indicating a much stronger rejection of the null. Together these results indicate that assigned cases look very similar ex ante but quite different ex post.

To proxy for legal risks, we rely on the data on pecuniary and jail penalties. Because legal risk is an ex-ante construct, we use predicted penalties as proxies. Specifically, we consider an information set that is available to an insider at the time of receiving the private tip to predict the value of each type of penalty. We form predictions using court fixed effects since these are formally exogenous predictors of penalties. Including other controls allows us to soak up the cross-sectional variation in traders' characteristics and validate the notion of the lack of significant assignment between such controls and penalties. For that, we specify the following model:

$$Penalties_i = a + b \times CourtFE_i + c \times Indiv_i + d \times TipperInsider_i + e \times Controls_i + error_i, \quad (17)$$

where $Penalties$ is either a pecuniary or a jail penalty, denoted $Penalty$ or $Jail$, respectively. We include a vector of court fixed effects as a natural predictor of the severity of penalties, as well as the individual characteristics contained in the vector $Indiv$. We also include $TipperInsider$, since receiving a private tip first hand could be regarded as a legal risk driver. Finally, we include a set of controls that include $Kyle$ and $Inforisk$.

The estimation results in Table V yield two interesting insights. First, legal jurisdiction is a

strong predictor of penalties. For example, the top three courts (SDNY, District of Columbia, and California) display positive and statistically significant coefficients. While the SDNY displays the largest fixed effect on pecuniary penalties, California displays the largest value for jail penalties. Second, *Penalty* and *Jail* are not significantly related to the predictors of insider trading activity included in *Kyle* and *Inforisk*. Individual characteristics estimates are not statistically significant, but, for the most part, display signs that are intuitive. For example, pecuniary penalties are positively related to age, being male, and working in the financial industry.

Next, for each insider trader, we use the predicted values from regression (17) to construct two measures of legal risk to be used in model (16): *PredJail* for jail and *PredPenalty* for monetary penalties. Again, because all regressors in (17) are predetermined relative to strategic trading decisions, these legal risk measures capture information sets ex ante. At the same time, one could be concerned that omitted variables driving the variation in trading decisions could also affect the value of penalties. The analysis in this section lessens such concerns, since we find that virtually none of the determinants of strategic trading decisions are related to these predicted regressors. Nonetheless, we explore several alternative identification strategies in Section 4.5 and Section 5.

4.4 Baseline Empirical Results

This section presents the baseline estimation results from equation (16) that characterize the relation between insider traders' strategic behavior and economic fundamentals and risks. Table VI displays the OLS estimation coefficients for the timing-related decision variables *Splitting* and *Duration* and the volume-related decision variables *Bet* and *Intensity*. All specifications include *Inforisk* and the two measures of predicted penalties as the leading independent variables. All standard errors are clustered at the trader level.[13] For *Splitting,* we include an indicator variable for cases with zero values to explore the intensive margin of the variable. To facilitate the proper interpretation of the results, we normalize the value of *Intensity* using its mean and standard deviation.

Columns (1) of Table VI reports the results for *Splitting.* Consistent with the theoretical pre-

---

[13]Clustering at the trader level allows us to capture the within trader dependence of error terms. In unreported results, we also consider clustering at the firm level to account for within firm dependence. The results from this alternative estimation produce slightly lower standard errors. Hence, we proceed with the more conservative findings.

diction, we find that the coefficient of *Inforisk* is negative and statistically significant. The effect is also economically substantial: cases in which $Inforisk=1$ display values of *Splitting* that are, on average, lower by about 18% of the cross-sectional standard deviation of the variable. Also in line with the theoretical prediction is the positive and statistically significant coefficient of *PredPenalty*, indicating that traders facing higher legal risk tend to split their trades more fully. Economically, a one standard deviation increase in *PredPenalty* increases *Splitting* by almost 15% of its cross-sectional standard deviation. The effect of *PredJail* is also positive, but statistically insignificant, and economically four times smaller. Perhaps surprisingly, traders reduce the degree of order splitting when *Realized Volatility* is high. We also note that the variables in *Indiv* that control for individual characteristics are not statistically significant predictors of *Splitting*.

Column (2) of Table VI reports the results for *Duration*. Consistent with the theoretical prediction, we find that the effect of *Inforisk* is negative and statistically significant. It is also economically large, since cases with $Inforisk=1$ exhibit levels that are lower by 33% of the cross-sectional standard deviation. The relation between *Duration* and legal risk is also negative, but it is only statistically significant for *PredJail*. A one standard deviation movement in the latter variable reduces *Duration* by about 10% of its standard deviation. The fact that higher legal risk induces earlier trades is consistent with the model analysis, but perhaps not surprising in light of the results for *Splitting*, since these two measures are, of course, related. However, for the case of *Duration* more specifically, a negative coefficient is also consistent with a simple legal risk intuition: if trades are detected, the insider trader would be in a better defensive position if the trades were more distant in time from the official corporate event. Turning to other determinants, similar to *Splitting*, *Duration* is not systematically related to individual characteristics. On the other hand, somewhat contrary to the model prediction, *Duration* is higher for trades associated with high values of *Strength*.

We now turn to *Bet* and *Intensity*, in columns (3) and (4) of Table VI. As expected, the coefficient of *PredPenalty* is negative and statistically and economically significant for both metrics. On the other hand, we observe no statistically significant relation between *Inforisk* and the informed volume.

Somewhat contrary to the model's intuition, insiders trade less aggressively when the private signal is more powerful. Such behavior is consistent with insiders targeting a given *nominal* monetary gain: ceteris paribus, if a given dollar amount is targeted, higher-value signals require lower trade volumes. The estimated coefficients of $Ln(mktcap)$ for *Bet* and *Intensity* illustrate the fact that dollar informed volumes are positively related to firm size, whereas the opposite is true for the informed volume *proportion.* The negative sign of *Intensity* is consistent with traders facing some form of capital constraint. Finally, traders in the financial industry trade more aggressive quantities. All the other individual coefficients are statistically insignificant.

The estimates of the coefficients defined here are broadly consistent with our theoretical predictions. In particular, for both measures of risk, we observe a positive relation with *Splitting* and a negative relation with *Duration.* The relation between *PredPenalty* and *Intensity* is negative, as predicted. The same is true for *PredJail*, but the relation is statistically insignificant. We also note that the measure based on jail penalties is a stronger predictor of *Duration,* suggesting that expected jail penalties can also be informative about strategic trading decisions.

Taken together, the results in this section yield three important insights. First, insiders consider legal risk in the timing of their trades, and they trade off such risk against information risk in a way that is broadly consistent with the model's predictions. Second, the decision about trading quantities is less influenced by information risk. Third, perhaps surprisingly in light of previous behavioral finance results, the variables that control for individual characteristics, such as age and gender, are not statistically significant predictors of strategic decisions. Decisions seem to be influenced to a much higher degree by the canonical determinants of profit-maximizing (rational) trading considered in Kyle models, such as the amount of noise trading, the fundamental uncertainty in asset value, and the realization of the private signal value. That said, even controlling for information and legal risk, our results also suggest that a simple Kyle model is unlikely to provide a full description of strategic decisions. Our findings suggest, that features such as risk aversion and capital constraints that are absent in the classic Kyle model are likely to play a role as well.

4.5 An Alternative Instrumentation of Legal Risk

As an alternative approach to identifying the coefficients of our model, we invoke the instrumental variables regression model in which legal risk, measured by *Penalty* or *Jail*, is instrumented using court assignments. Our results in Table C2 of the Internet Appendix support the validity of using court fixed effects as instrument. The exclusion restriction requires that court assignment can only impact the traders' strategies through its influence on the insider trading penalties. We believe this restriction is quite plausible given that insiders are unlikely to choose their geographical location in anticipation of illegal insider trading. Also, our results show that court fixed effects do not explain individual traders' characteristics. Hence, it is unlikely that judges pass their verdicts based on anything else other than the crime itself. We estimate the IV regression using a 2SLS procedure. The untabulated results indicate the relevance of the instruments. For both penalty and jail, the F-statistic is greater than a critical cutoff level of 10. Hence, the instruments are statistically strong. We report the results of the second-stage regression in columns (1) to (4) of Table VII. The results are qualitatively consistent with those reported for the OLS specification. A greater degree of information risk makes investors less conservative in terms of trading greater quantities and splitting their trades less. Instrumented legal risk, in turn, makes investors more conservative in that they split their trades more and trade smaller quantities.

The difficulty with interpreting our IV results is that the full set of 77 candidate instruments likely contains many variables that contribute little to no additional information on court preferences. These variables may add noise to the estimation and decrease prediction accuracy. To address this concern, we employ shrinkage procedures to reduce dimensionality and isolate the key sources of variation in a model (see Hastie et al. (2009)). While it is acknowledged that these procedures introduce bias into the estimation of model parameters (first-stage coefficients), the potential variance reduction has generally been shown to result in improved prediction accuracy (Leeb and Potscher (2008)). We follow recent advances in shrinkage methods with special applications to instrumental variables. We adopt the post least absolute shrinkage and selection operator (Post-Lasso) using the implementation of Belloni et al. (2012). We present the results for the main regressors in columns

(5) to (8) of Table VII.[14] The results from this estimation closely mimic those from regular IV which suggests that the full set of instruments may not add too much noise. At the same time, the model is quite stringent in terms of the number of instruments it chooses in the post-estimation, varying between seven and 11. This result clearly underscores the efficiency of the method.[15]

The fact that strategic decisions are affected by legal penalties should be of interest not only to academics but also to regulatory agencies and law makers alike. Given the importance of this finding, we end this section by noting a potential concern with our identification scheme, where, unlike for trading strategies, exact measures of detection probabilities and ex-ante conditional penalties are not available. Given that we cannot entirely rule out measurement error in our proxies, or formally test the unlikely but problematic possibility of detection probabilities and penalties being negatively related, in the following two sections we exploit a comprehensive set of plausibly exogenous shocks to the components of legal risk.

5 Time-Series Variation in Legal Risk

The model in Section 3 predicts that, if legal risk increases, the insider should act more prudently. Specifically, the insider trades lower quantities, increases *Splitting,* and reduces *Duration.*[16] While the stylized insider in the model only cares about the *total* expected legal cost, we are interested in empirically testing whether real insiders indeed respond to (i) changes in the probability of trade detection, (ii) changes in the probability of prosecution (conditional on detection), and (iii) changes in penalties. With that goal, in this section we consider sources of plausibly exogenous shocks to the components of legal risk so as to buttress the identification of insiders' responses. Sections 5.1 to 5.3 evaluate such responses from the perspective of strategic trading decisions. In turn, Section

---

[14]For parsimony, our IV results only report results on the two main driving forces of our model: information risk and legal risk. At the same time, as pointed by Belloni et al. (2012), the statistical significance of the estimated coefficients can only be legitimately assessed for instrumented variables and not controls.

[15]In untabulated tests, we have also included as instruments the court fixed effects interacted with year of insider trading to allow for the possibility that the impact of various courts may vary over time. The results using both IV implementations are qualitatively very similar to those we report in the paper, which suggests that court effects are likely quite persistent over time, on average.

[16]We note that a decrease in *Duration* could also be regarded as intuitive for nonmodeled reasons, such as if the insider believes that the regulator is screening trades that occur near the corporate announcement.

evaluates the same from the perspective of engaging in insider trading.

5.1 Evidence from the Dodd–Frank Act

As a reaction to the financial crisis and the negative public sentiment about the status quo of the financial industry, on July 21, 2010, President Obama signed into law the Dodd–Frank Wall Street Reform and Consumer Protection Act. This landmark legislation strengthened and expanded the SEC's regulatory oversight and enforcement authority over securities markets.[17] Perhaps equally important, as a component of this changing regulatory atmosphere, the SEC strengthened its investigation focus on more prominent and economically substantial insider trading investigations, imposing larger penalties. For example, besides the case of SAC Capital discussed above, the SEC brought to court Galleon Group's Raj Rajaratnam, who at the time managed over \$7 billion in assets, and Rajat Gupta, head of McKinsey & Co, generating strong attention in the media on Wall Street (e.g., Raghavan (2015)). To validate the economic importance of these developments, Figure 8 displays the time series of the annual numbers of insider trading jail sentences and the total monetary values of insider trading penalties. Starting in 2011 and up to 2013, we observe an economically significant upward shift across both series.[18] In light of these factors, therefore, we treat this period as one in which expectations regarding legal penalties receive a positive shock. To test the effect of the shock, we set 2008–2010 as a natural control period. Such a symmetric time window reduces the possibility of capturing additional regulatory changes over more extended periods that could affect the results.

---

[17]Furthermore, in the same period, the Obama administration increased the SEC's budget and that of related government agencies. According to the SEC Annual Reports, the SEC budget over 2008–2010 increased by 3.6% relative to the preceding three-year period, 2005–2007. At the same time, the budget in 2011–2013 increased more aggressively, by 21.8%, relative to the previous three years. Del Guercio, Odders-White, and Ready (2017) report that up to 36% of the SEC budget is allocated to the Enforcement Division.

[18]As an example, record-breaking criminal and civil penalties were applied to insider trading defendants in 2011. On the criminal side, federal courts sentenced a record number of insider trading defendants and sentenced a higher proportion to prison than in any prior year. The vast majority of the sentences, however, remained below the range of the sentencing guidelines and the recommendations of prosecutors. On the civil side, the SEC settled or secured judgment in almost twice the number of insider trading cases it had brought to final judgment the year before.

Figure 8. Insider trading penalties and jail sentences, 1999–2015
Next, we estimate the following regression model:

$$StrategicDecision_i = a + b \times DoddFrank_i + c \times Controls_i + d \times Court_i + \text{error}_i,$$

where *DoddFrank* is an indicator variable equal to one for insider trades taking place between 2011 and 2013, and zero for the trades between 2008 and 2010. The control variables are as in the baseline specification (16). We also include court fixed effects to control for the possibility that the legal jurisdiction is driving the strength of penalties assessed to insiders.

Columns (1) to (4) of Table VIII present the results. We observe that the shock affects trading decisions. In particular, we find that *Duration* decreases, as hypothesized. The change is statistically and economically significant, since the coefficient decreases by 19.93% in 2011–2013 relative to its standard deviation. Both *Bet* and *Intensity* display negative coefficients, as hypothesized, but they are not statistically significant. On the other hand, we do not find evidence of a positive relation with *Splitting*. In sum, we find strong evidence that informed trades occur earlier, on average, during the shock period, and there is weak evidence that the informed volume decreases overall.

35

5.2 Evidence from the Newman Ruling

The time-series evidence in Figure 8 also identifies a sharp decrease in pecuniary and jail penalties between 2014 and 2015. This remarkable reversal in the severity of penalties resulted from a specific Supreme Court ruling involving two hedge fund managers, Todd Newman and Anthony Chiasson. Both managers were brought to trial but subsequently released. The Supreme Court judges' view was that no offense is committed unless a corporate insider acting as the tipper receives money or valuable property, such as jewelry, in exchange for leaking material information. Because the defendants were several layers removed from the original information leaks, and no evidence of payments was found, it was hard for the prosecutors to prove with near certainty that these managers were aware of the wrongful acquisition of that information.

This stricter interpretation of the law torpedoed a number of insider-trading prosecutions across the Second Circuit, which includes New York and Connecticut, where many hedge funds are based and most such cases are brought.[19] The consequences of the ruling were immediate and dire. Bharara, U.S. Attorney of Manhattan, was forced to dismiss nearly a dozen of the 111 insider trading cases that he had brought to court since assuming his post in August, 2009. Among the cases that were abandoned were several in which he had already obtained guilty pleas. Many argued that 2014 significantly reduced the expected legal risk associated with insider trading. Such a view is formally supported by the time-series variation in assessed penalties and jail sentences.

We, therefore, regard the Newman ruling as a negative shock to the probability of viable prosecution. For that scenario, we should observe the opposite effect on strategic decisions relative to that of Dodd–Frank. To test the prediction formally, we define an indicator variable *Newman* as equal to one for the period 2014–2015, and zero for the period 2011–2013. Subsequently, we estimate the baseline regression model with *Newman* as a main control variable. The results are presented in columns (5) to (8) of Table VIII. Consistent with lower prosecution risk and less prudent behavior, the estimated coefficients for *Duration* and *Intensity* are positive and statistically significant. Both effects are economically large. Additionally, as predicted, the effects on *Bet* and *Splitting* are

---

[19]See, for example, https://www.nytimes.com/2016/08/02/business/dealbook/supreme-court-could-rewrite-insider-trading-law.html.

positive and negative, respectively, but statistically insignificant. The evidence therefore supports the view that traders responded to the weak enforcement environment after the Newman ruling by trading more aggressively.

5.3 Evidence from Internet Search Trends

Our model and simple economic intuition suggest that, if the probability of enforcement actions increases, legal risk should impact insider traders' strategies more heavily. In previous sections, we evaluated this prediction using time-series variation in legal or regulatory actions, a source of probability shock that can naturally be regarded as *objective.* In this section, instead, we empirically assess this prediction from the perspective of a *subjective* assessment of such probability. We proxy for the latter exploiting the time-series variation in the public's attention to insider trading, as measured by Google Trends. Specifically, we track online searches for the phrase *illegal insider trading* for the available period, 2004 to 2015. The monthly variation in the search activity is displayed in Figure 9. Although the series seems to be mean reverting, there are identifiable episodes with large spikes in values, several of which can be linked with the notorious insider trading cases discussed above.

Since the relation between online searches and the probability of legal enforcement is likely to be nonlinear, we specify a cutoff level equal to the 80th percentile of the unconditional distribution of the Google Trends measure and define an indicator variable, *InsiderTrend,* equal to one if the monthly value is above this cutoff. We regard *InsiderTrend*=1 months as periods where the fear of trade detection or legal prosecution increases. Subsequently, we estimate the following regression model:

$$StrategicDecision_{it} = a + b \times InsiderTrend_{it} + Controls_{it} + d_{year} + \text{error}_{it},$$

where d_{year} corresponds to year fixed effects.

Table IX presents the results. The *Insider Trend* coefficient of *Splitting* is positive, indicating that traders are more likely to split their trades in periods of higher perceived risk. Additionally,

Figure 9. Internet search intensity for the term *insider trading*, January 2004 to December 2015
Source: Google Trends.

the coefficients of *Bet* and *Intensity* are negative and statistically significant, as predicted. Overall, the qualitative response of insiders' strategic decisions is consistent with the predicted response to a heightened subjective probability of enforcement actions.

5.4 Legal Risk and Private Signal Choice

In previous sections, we analyzed the impact of expected legal costs on the profile of insider trading strategies. We now assess the impact of legal costs from a different perspective: the ex-ante benefits of engaging in insider trading. Ceteris paribus, a rational trader who internalizes legal risk would be less willing to act on any given private signal if either the probability of enforcement or the conditional penalty increases. In other words, high expected legal costs require high expected benefits for an insider to take action. Consequently, following the seminal ideas of Becker (1968), we hypothesize that, in response to increasing legal risk, insiders could rationally become more selective and, thus, concentrate on private signals of higher values. If private signals of relatively low values are dropped, because they are not worth the risk, the consequence of such behavior

38

should be an increase in the selected signals' average value.

We test this hypothesis by comparing the average value of PSV as in (1) for the subsamples described in Section 5.1, with the period from 2008 to 2010 representing low expected legal cost and that from 2011 to 2013 representing high enforcement risk. Formally, we conjecture that $b > 0$ in the following specification:

$$PSV_j = a + b \times DoddFrank_j + \text{error}_j.$$

Table X shows the results. Consistent with our hypothesis, the average private signal value is significantly higher in times of high enforcement risk, at 48.5%, versus 34.83% in times of low enforcement risk. The difference is both economically and statistically highly significant.

For robustness, we replace $DoddFrank$ by $InsiderTrend$, as defined in Section 5.3. The intuition is similar: cases contemporaneous with $InsiderTrend = 1$ should display higher average values of PSV if traders pass on low-value signals when the perceived legal risk is high. Table X shows that the difference between these two subsamples (43.66% vs. 32.05%) is also economically and statistically significant.

We also note that the same conclusion is reached by replacing PSV with $Strength$, that is, measuring the value of the private signal from T_{first} instead of T_{info}. The bottom panel of Table X shows that the differences in the mean values are significant, although quantitatively more moderate: 31.9% versus 25% for $DoddFrank$ and 26.37% versus 22.09% for $InsiderTrend$.

Overall, the evidence on the distribution of private signals complements our evidence on strategic trading in the previous sections and further supports the notion that insider traders internalize legal risk.

6 Cross-Sectional Variation in Legal Risk

In this section, we exploit sources of plausibly exogenous cross-section variation in legal risks. Section 6.1 stresses the severity of legal penalties, while Section 6.2 focuses on the probability of insider

trade detection. In turn, Section 6.3 better relates to the probability of prosecution. As in Section 5, the underlying hypothesis in all cases is that, if legal risk increases, the insider should act more prudently. To facilitate relations, we provide a test taxonomy in Table D3 of the Internet Appendix.

6.1 Evidence from the SDNY

We take advantage of the anecdotal evidence on insider trading prosecutions suggesting that the Southern District of New York (SDNY) became a renownedly tough court under the reign of Preet Bharara.[20] Bharara was appointed in 2009 and continued until 2017. However, the 2014 Supreme Court Newman ruling discussed above weakened his power substantially.[21] In this regard, we argue that potential illegal traders faced particularly strong legal penalties during the early part of his tenure, from 2009 to 2013, a period we call the *Bharara* period.

To evaluate the incidence of such cross-sectional variation, we compare the strategic decisions of traders under SDNY jurisdiction to those investigated by other jurisdictions during the Bharara period and during adjacent periods. Under the hypothesis that the Bharara period had a positive impact on expected penalties, one would expect insiders located in the SDNY to behave more prudently then. Next, we estimate the following regression model:

$$StrategicDecision_i = c \times Bharara_i + d \times SDNY_i \times Bharara_i \tag{18}$$
$$+ e \times Controls_i + f \times Court_i + \text{error}_i,$$

where *SDNY* is an indicator variable equal to one if the insider case is subject to prosecution in the SDNY, and *Bharara* is an indicator variable equal to one for the period 2009–2013, and zero for the adjacent periods 2006–2008 and 2014–2015[22]. The coefficient of interest is *d*. The set of controls

---

[20]For example, The New York Times argued that Bharara was one of "the nation's most aggressive and outspoken prosecutors of public corruption and Wall Street crime" (see https://www.nytimes.com/2017/03/10/nyregion/preet-bharara-us-attorney.html).

[21]Consistent with this view, see, for example, See also https://nypost.com/2015/10/05/supreme-court-rejects-insider-trading-case-in-setback-for-bharara.

[22]We choose this period to match the duration of Bharara's ultimate power. Because his power has weakened after 2013, we use the two years after 2013 and the three years before 2009. The results are very similar if we use the five-year period from 2004 to 2008 instead. The results weaken somewhat if we used the entire period from 2009 to 2015 as a treatment period, which is consistent with our view on the change in Bharara's power to push through

mimics that in the baseline specification (16). To show the direct effect of the SDNY, we exclude the constant term in the regression.

Columns (5) to (8) of Table XI present the results. We find a statistically and economically significant negative effect on insider trading quantities. Traders under SDNY jurisdiction display values of *Bet* and *Intensity* that are, respectively, 42.9% and 27.19% lower during Bharara's tenure relative to the standard deviations of these variables. The coefficients of *Splitting* and *Duration*, on the other hand, are statistically insignificant.

6.2   Evidence from the WRP

To evaluate changes in detection probabilities across traders, we exploit a a hand-collected sample of trades identified through the SEC's WRP, implemented in 2011 as part of the Dodd–Frank Act. The underlying idea of the program is to use monetary payments to incentivize whistleblowers to provide regulators with *original information* on insider trading activity. The program defines original information as information that is (i) derived from the independent knowledge or analysis of a whistleblower, (ii) not known to the SEC from any other sources, and (iii) not exclusively derived from an allegation made in a judicial or administrative hearing, governmental report, hearing, audit, or investigation or from the news media. Since such insider traders are not identified by any other means, it seems plausible to regard this group as more highly skilled.[23]   From 2011 to 2015, our sample contains 187 different cases, 47 of which are investigated through the WRP and 140 of which do not have a precise source of investigation. The latter could be the result of SEC/Financial Industry Regulatory Authority data analyses or based on other tips, such as those coming from brokers or stock exchanges. Table D4 in the Internet Appendix summarizes various trading characteristics and shows that the two sets of cases are not very different from each other along most dimensions. The only notable difference is that WRP cases involve, on average, companies with greater market capitalization.

---

insider cases.

[23]Of course, there is also a chance that a trader in this sample is not sophisticated but simply lucky. The identification ability of this scheme relies on a population-wide feature: the probability of being detected by regulatory agencies decrease in one's trading skills.

Sensitivity to legal risk, among other factors, could vary across traders, depending on the trader's skills or ability. We conjecture that highly able traders internalize the risk of being detected and could develop superior skills at camouflaging their trades. Relative to poorly skilled individuals who might not fully grasp the relation between trades and detection risk, high-ability traders could be more sensitive to a positive shock to legal risk such as that considered in Section 5.1. To test such a hypothesis, we need to classify traders across skill levels. Naturally, SEC investigations do not provide such a classification. In principle, one could rely on a skill measure based on the characteristics of detected trades, for example, whether traders display high or low *Splitting* values. However, such an ex-post classification would pose additional identification challenges. For example, depending on market conditions, a highly skilled trader could find it optimal to concentrate trades within a relatively short period if that decision lowered the probability of detection.

Instead, to select skilled traders, we rely on a different identification scheme based on the trader's detection source. In particular,

Subsequently, we assess whether skilled traders respond differently to changes in the enforcement environment following the adoption of the Dodd–Frank Act. Formally, we estimate the following model:

$$StrategicDecision_i = a + b \times WhistleB_i + c \times DoddFrank_i + d \times WhistleB_i \times DoddFrank_i$$
$$+ e \times Controls_i + f \times Court_i + \text{error}_i,$$

where *WhistleB* is an indicator variable equal to one for traders identified through the WRP, and *DoddFrank* is defined as before. The coefficient of interest is d, which measures the sensitivity of strategic decisions to the trader detection source. Columns (1) to (4) of Table XII present the results. Sophisticated investors are more likely to reduce their trade volume when facing greater enforcement risk. For *Bet*, the interaction term coefficient is negative and statistically significant at the 5% level. For *Splitting,* the coefficient of the interaction term is positive, with a t-statistic slightly above 1.5, suggesting that this group of traders is more likely to spread trades more extensively when facing a positive enforcement shock than the average trader in the sample.

6.3 Evidence from Lawful Informed Traders

Not every insider trading prosecution is well grounded. As in any legal issue, the judicial process can identify situations in which no crime is committed. In the context of insider trading, such a situation corresponds to a well-informed individual who trades lawfully. We view such cases as providing a unique opportunity to understand the strategies of individuals who are (i) are trading on precisely identified private information and (ii) are less likely to design their strategies with legal risk in mind. To the extent that such traders do not internalize legal risk as fully, our model predicts that they should split their trades less extensively, display higher durations, and trade more aggressively. Accordingly, we collect a set of 19 investigations that were brought to court by the SEC, but were eventually dismissed by a judge for lack of supporting evidence.[24] Among others, our sample includes the cases of Newman and Chiasson discussed before, as well as the case of Michael Steinberg from the SAC Capital. To strengthen identification, we compare the trading strategies of these unconvicted traders to those drawn from a sample of convicted, but otherwise similar individuals. Specifically, we focus on a subset of traders with relatively low penalties corresponding to the 75th percentile of the distribution, excluding reckless insider traders such as Rajaratnam and Martoma. Such an approach allows for a maximum penalty of $140,000 and results in 190 trades from 38 different investigations.

Formally, we estimate the following regression model:

$$StrategicDecision_i = a + b \times Lawful_i + c \times Controls_i + \text{error}_i, \tag{19}$$

where *Lawful* is an indicator variable equal to one for trades deemed as legal by the corresponding federal court, and zero for trades performed by traders facing penalties. All the control variables are as in Section 4.

The results, in Table XIII, show that lawful traders exhibit lower values of *Splitting*, higher values of *Duration*, and higher values of *Intensity*. All of the associated coefficients are statistically

---

[24]Of course, the fact that a case was dismissed does not necessarily imply that, say, a second judge would also have concluded that the trader is not guilty. We are relying on a population-wide association between acting lawfully and the probability of not being found guilty.

significant. The differences are also economically meaningful. Relative to the corresponding sample standard deviations, the values of *Splitting* are 38.24% lower, while the values of *Duration* and *Intensity* are 61.12% and 68.42% higher. In sum, the evidence in this section provides further support for the notion that strategic decisions are affected by legal risk.

Overall, the results in the cross-sectional analyses provide supporting evidence of the role of traders' abilities and the legal profile of the court and prosecutors carrying out the insider trading investigation.

7   Discussion of Implications

In this section, we provide a short discussion of the implications of our work and suggest directions for future research.

7.1   Strategic Use of Private Information

The simple framework developed in Section 3 highlights the role of information risk and legal risk but also embeds the basic ingredients of the canonical Kyle model. Therefore, several of our findings in Section 4.4 are informative about the empirical connections between such ingredients and insiders' strategies. To sum up, we find that the basic predictions from the Kyle model on strategies are confirmed in the data. In particular, the value of information, its precision, the volatility of asset prices, and the amount of noise trading play an important role in the design of trading strategies. Thus, our results complement the supporting evidence for the Kyle model by Koudijs (2015), which is based on return correlations.

At the same time, having controlled for the elements of Kyle's model, we do not find strong evidence that personal characteristics, frequently highlighted in the behavioral finance literature, such as gender, age, or corporate role, play an equally central role. However, we empirically show that, although given several weeks to trade in most cases, a non-negligible fraction of investors do not split trades at all. We note that, while interesting per se, such a finding is not direct evidence of lack of rationality or a violation of the Kyle model. Unmodeled frictions, such as attention costs,

for example, could induce rational investors to limit the scope of order splitting.

7.2   Relations to Other Informed Traders

While illegal insiders are a subset of a broader group of informed traders, we do not claim that our findings can be automatically extrapolated to any type of such traders. For example, the properties and duration of private signals could be different elsewhere. A hedge fund manager that generates his or her own signal through fundamental research and expects the market price gap to disappear over several years could behave more cautiously. On the other hand, the perceived absence of legal risk and the fear of information disappearing could result in such managers behaving more aggressively. To this end, Yan and Zhang (2009) show that active fund managers with shorter investment horizons generate higher alphas. The net effect of these factors is not obvious ex ante: insider traders could be more or less aggressive than other informed traders.

We can, however, provide some perspective on the generalizability of our findings regarding the role of legal risk. The test in Section 6.3 on lawful traders, who are unlikely to internalize legal risk, provides a valuable insight, since we find that lawful traders trade somewhat more aggressively. At the same time, untabulated results suggest that, otherwise, lawful traders display similar patterns of strategic behavior as those who face penalties. For example, information risk reduces the value of *Duration* and *Splitting* in both cases. Therefore, the available evidence, although limited in scope, suggests that our findings can still be helpful in understanding the strategies of other informed traders. It would be interesting for future research to provide direct evidence from different groups of informed traders.

7.3   Regulatory Actions

Perhaps the most important implication of our study is that regulatory and legal actions *do affect* insider trading. Exploiting multiple plausibly exogenous sources of variation in legal risk, we show that an increase in such risk induces insiders to adjust their strategies; they become more conservative. Such a finding provides useful empirical validation of the deterrence power of the SEC's

actions.[25] Moreover, by developing similar institutional frameworks, regulatory agencies in countries where the enforcement of insider trading laws is currently weak can, therefore, hope to influence the investment environment in their capital markets. In this regard, our micro-level evidence complements the seminal international study by Bhattacharya and Daouk (2002), who find that firms' costs of capital are affected by the initiation of enforcement actions against insider trading, rather than the mere introduction of laws.[26]

A logical consequence of this finding is that, if a regulatory body decides to strengthen its data-based ability to detect illegal trading, the effect on insider strategies could, in turn, make it more difficult for the regulators to detect such misconduct. Whether such a cat-and-mouse game leads to a greater proportion of illegal trade detection over the long run and whether, more broadly, it represents an efficient use of regulatory resources are open empirical questions. In light of the growing sophistication of trading technologies (e.g., trading algorithms, exchange routing systems, complex order types), however, our results rationalize the adoption of detection mechanisms that are *independent* of the dynamics of trading, such as the Whistleblower Reward Program.

7.4 Informativeness of Asset Prices

In this paper we characterized the value of insiders' private signals and the trades motivated by them. Of course, in the general equilibrium, the trading strategies of the insider impact the degree of information transmission. A thorough characterization of the process of information transmission is beyond the scope of this study.[27] We can ask, however, to what extent do the trades of insiders fully reveal the information contained in the private signals?

We address this question by studying the price adjustment process between the open, on day T_{first}, and the day immediately after the public release of information, $T_{\text{public}} + 1$. In the interest of space, we relegate the details of the calculations and a graphical representation to Section E of the Internet Appendix. The analysis delivers three insights. First, relative to counterfactual risk-

---

[25]The deterrent effect of legal sanctions cannot be taken for granted. For example, Piliavin et al. (1986) find that noncorporate criminals are influenced by anticipated returns but not by anticipated penalties.

[26]See also the international study by Fernandes and Ferreira (2009) regarding the informativeness of asset prices.

[27]See Vives (2008, ch. 9) for an excellent analysis of the speed of information aggregation in models with long-lived private information.

neutral traders who would smooth information transmission until the private signal is fully revealed at the announcement date, in the spirit of the continuous-time analyses of Kyle (1985) and Back (1992), insider traders here impound less information into prices. The top panel of Figure E4 in the Internet Appendix shows that the median cumulative return at the end of the trading period is about 58.1% of the *PSV*. Second, although the process of information aggregation is visible from the first period of trading, about half of the information transmission takes places in the last round of trades preceding the public announcement. Third, we observe a striking contrast among corporate event types. Consider the middle and bottom panels displaying earnings announcements and M&A events, respectively. We can see that scheduled earnings events are characterized by *less* information aggregation overall. Indeed, only 30% of the median *PSV* is reflected in prices before the public announcement. Moreover, earnings display a rather flat time series of cumulative returns. The bulk of the price effect is incorporated into prices during the first part of the trading period.

The finding that insider traders internalize legal risk is a natural explanation to the seemingly weak amount of information aggregation prior to public announcements, although additional factors such as capital constraints could also play a role. Such finding also implies that regulators should unequivocally factor the potential social costs derived from the weaker informational efficiency of securities prices, as previously highlighted by Manne (1967), Leland (1992), and Bernhardt et al. (1995), among others. Further study of the general equilibrium effects of enforcement actions, particularly its impact on other market participants, such as long-term investors and market makers, would be a promising research endeavor that would help to clarify the legal effects on price informativeness, firm performance, and capital allocation.

8 Concluding Remarks

The debate whether insider trading should be illegal, and under what circumstances, has a long tradition in economics and finance. The dominant view that promotes enforcement actions highlights the potential to reduce the cost of firms' capital and increase investment (e.g., Manove (1989);

47

Ausubel (1990); Easley and O'Hara (2004)). [28] Our goal is not to settle this debate. However, we believe that our results provide valuable insights regarding the potential costs impounded in price informativeness. From an ex-ante perspective, and consistent with Becker's view of rational crime, the results in Section 5.4 suggest that insider traders could *refrain* from trading whenever the value of their private signal is relatively low. Such choices could hamper stock price informativeness at the individual firm level, a concern that is particularly pressing, given the recent explosion in popularity of exchange-traded funds and similar portfolio-level investment vehicles. This notion echoes the predictions of a theoretical model of Kacperczyk et al. (2018), who show, in general equilibrium, that the shift of holdings from informed to uninformed investors reduces price informativeness. Second, by affecting the design of trading strategies, regulations are likely to affect price informativeness, *even* when insider trading occurs. Indeed, theoretically and empirically, we find that legal risk induces insiders to trade lower quantities and to concentrate relatively more volume earlier.

Table I

Insider Trading Investigations and Penalties: Summary Statistics

We classify the sample of SEC insider trading cases. Firms per case is the number of distinct companies reported in a given case; traders per case is the number of distinct traders involved in a given case; trades per trader is the number of trades executed by insider in all cases he/she appears in the data; trades per firm is the number of trades executed by all insiders trading a given firm's shares; trader finance background is the percentage of insiders who have finance job; trader top executive is the percentage of insiders who hold executive positions in their respective companies; reported profit is the dollar profit realized on a given trade (in '000).

A. General characteristics	mean	median	SD	min	max
Firms per case (N=840)	2.07	1	3.15	1	26
Traders per case (N=1079)	5.71	4	5.21	1	25
Trades per trader	20.22	10	24.32	1	97
Trades per firm	18.53	13	21.24	1	126
B. Penalties	mean	median	SD	min	max
Trader penalty (USD m.)	2.85	0.20	14.03	0	156.61
Total penalties per case (USD m.)	11.74	1.25	32.68	0	177.21
SD of penalties within case (USD m.)	3.16	0.08	11.37	0	89.64
Jail sentence (%)	10.48	-	-	-	-
Percentage of jailed traders (within case)	10.43	0	22.24	0	100
Probation (%)	23.55	-	-	-	-
Dropped (%)	12.40	-	-	-	-
C. Most active courts (N=77)	number	percentage			
Southern District of New York	144	30.44%			
District of Columbia	29	6.13%			
Central District of California	26	5.50%			

Table II

Summary Statistics: Corporate Events, Trading Instruments, and Industries

We classify the sample of SEC insider trading cases based on event type (M&A, earnings announcements, general business events, shares offerings, and dividend changes), information sign (good news/bad news), and trading instrument (stocks, options, ADS, and bonds).

Event type	Number of cases	Percentage
Mergers & Acquisitions	360	55.90
Earnings announcements	97	15.06
General business events (patents, trials)	69	10.71
Shares offerings & tenders	52	8.07
Dividend changes & buybacks	14	2.17
Other (restatements/fraud/manipulation)	52	8.07
Information sign		
Good news	664	71.86
Bad news	260	28.14
Trading instrument		
Stocks	3,392	67.06
Options	1,610	31.83
ADS	44	0.87
Bonds	12	0.24
Distribution of trades by industry (SIC2 codes)		
Chemicals (28)	752	16.09
Business Services (73)	673	14.40
Electronic Equipment (36)	494	10.57
Measuring and Controlling Equipment (38)	318	6.80
Industrial and Commercial Machinery (35)	220	4.71
Depositary Institutions (60)	192	4.11
Wholesale Trade: Durable Goods (50)	138	2.95
Engineering and Management Services (87)	132	2.82
Wholesale Trade: Nondurable Goods (51)	127	2.72
Oil and Gas Extraction (13)	103	2.20

Table III

Dependent and Control Variables: Summary Statistics

Splitting is the difference in number of days from the first to the last trade, scaled by the number of days from the date of information arrival until the day information is public. *Duration* is the time-weighted average of relative trade sizes over the two equal-length time periods splitting the time between the first and the last time the insider trades. *Intensity* is the maximum over all traded assets of the asset-specific trade size relative to the volume in the same asset. *Strength* is the return on information recorded from the open of the day when the insider trades until the open of the day following the public disclosure of information; *PSV* is the return on information recorded from the open of the day when the insider receives information until the open of the day following the public disclosure of information; *Realized Volatility* is the 30-minute return volatility of a traded stock; *Volume Vol* is the volatility of trading volume; *Tipper Insider* is an indicator variable equal to one if the insider is either a tipper or a trader in a case; *Traders* is the number of distinct traders involved in trading of a given stock and case; *Ln(mkt. cap)* is the natural logarithm of the firm's market capitalization. *PredPenalty* and *PredJail* are derived in Table V.

Characteristic	mean	median	st. dev.
Dependent Variables

TABLE IV
Information Risk and Action Delay

The dependent variable is *Action Delay* (defined as the difference in number of days from the date when the trader receives information until the first time she trades, scaled by the number of days from the date of information arrival until the day information is public). *Executive* is an indicator variable equal one if the trader is a corporate executive (vice-president rank or higher) and zero otherwise; *Finance* is an indicator variable equal one if the trader works in the finance industry and zero otherwise; *Age* is the age of trader in years; *Gender* is an indicator variable if a trader is male, and zero if a trader is female. All other controls are defined in Table III. ***, **, * denote 1%, 5%, and 10% level of statistical significance, respectively.

Table V

Determinants of Monetary Penalties and Jail Sentences

Penalty is a dollar amount of assessed penalty (in $million). *Jail* is an indicator variable equal to one if an insider receives a jail sentence, and zero, otherwise. All controls are defined in Table III. Court fixed effects are related to the court in which the settlement takes place. All controls are defined in Tables III and IV. ***, **, * denote 1%, 5%, and 10% level of statistical significance, respectively.

Internet Appendix for "Becker Meets Kyle: Inside Insider Trading"

Marcin Kacperczyk[*]   **Emiliano S. Pagnotta**[†]

This Version: August 6, 2019

A   Appendix to Section 1

This appendix provides background on the legal process of insider trading investigations. Moreover, to illustrate the main elements of an insider trading case, the appendix also considers the case of Matthew Martoma's trades in Elan and Wyeth. Supplemental tables are presented in the last section.

A.1   Background on Insider Trading

Insider trading is a term that includes both legal and illegal conduct. The legal variety is when corporate insiders—officers, directors, large shareholders, and employees—buy and sell shares in their own companies and report their trades to the SEC. Legal trading also includes, for example, someone trading on information that was overheard between strangers sitting on a train or when the information was obtained through a nonconfidential business relationship.

The illegal variety is not defined homogeneously around the world. In the United States, the legal framework prohibiting insider trading was established by Rule 10b-5 of the Securities Exchange Act of 1934, which specifies that illegal insider trading refers to "buying or selling a security in breach

[†]Imperial College London. Email: e.pagnotta@imperial.ac.uk

of a fiduciary duty or other relationship of trust and confidence, while in possession of material, nonpublic information about the security." Under the classical view of insider trading, a trader violates Rule 10b-5 if trading on material, nonpublic information about a firm to which the trader owes a fiduciary duty. Information is deemed *material* if a reasonable investor would consider it important in deciding whether to buy or sell securities. In recent decades, the scope of what constitutes illegal insider trading has increased. In particular, the 1997 Supreme Court case of *United States v. O'Hagan* upheld the SEC's authority to enforce insider trading under the so-called misappropriation theory. Under this theory, it is a violation of Rule 10b-5 to intentionally misappropriate and trade on confidential information in "breach of a duty owed to the source of the information." What constitutes such a violation of duty is a controversial legal issue.[1]

The consequences of being found liable for insider trading can be severe. Individuals convicted of criminal insider trading can face up to 20 years of imprisonment per violation, criminal forfeiture, and fines of up to $5,000,000 or twice the gain from the offense. A successful civil action by the SEC could lead to the disgorgement of profits and a penalty not to exceed the greater of $1,000,000, or three times the amount of the profit gained or loss avoided. The common rule is that the penalty is equal to the size of the profits realized in the case, in addition to the forfeiture of the profits realized in the case. In addition, the court requires the insiders to pay interest on the profit amounts and typically bars convicts from trading activities for a substantial period. Moreover, individuals can be barred from serving as officers or directors of a public company or, in the case of licensed professionals, such as attorneys and accountants, from serving in their professional capacity before the SEC.

---

[1]Despite the aforementioned increased scope, finding a trader guilty of insider trading is not easy. The legal practice of insider trading asserts that to find a tippee criminally liable for insider trading, federal prosecutors must prove all of the following elements: (i) the insider had a fiduciary duty; (ii) the insider breached that duty by disclosing confidential information to a tippee; (iii) the tip was made in exchange for a personal benefit, meaning a benefit of some consequence; (iv) the tippee knew of the tipper's breach (that is, the tippee knew the information was confidential and divulged it for a personal benefit); and (v) the tippee nevertheless used that information to make a trade. Bhattacharya (2014) provides an insightful overview of the legal arguments.

A.2   A Tale of an Insider Trader

Between 2006 and 2010, Matthew Martoma worked at CR Intrinsic, an unregistered investment adviser, serving as a portfolio manager from 2008 until his departure. Martoma perpetrated the insider trading scheme with Sidney Gilman, a professor of neurology at the University of Michigan.[2]

Gilman served as a consultant to Elan (ELN) and Wyeth (WYE), two pharmaceutical companies, from 2003 until 2009. Between 2006 and 2008, Elan and Wyeth jointly conducted a Phase II clinical trial for a potential drug, called bapineuzumab, to treat Alzheimer's disease. As a consultant, Gilman had continuous access to material nonpublic information concerning this trial. Among many duties, Gilman agreed to present, on behalf of Elan and Wyeth, the Phase II trial results at the International Conference on Alzheimer's Disease, a medical conference that was scheduled to be held on July 29, 2008. As a result of agreeing to serve as the presenter, Gilman was given access to the results approximately two weeks prior to the July 29 announcement. By virtue of his role in the clinical trial, Gilman owed Elan a duty to hold in strict confidence all information he learned in connection with his participation in the clinical trial and to use such information only for Elan's benefit.

Gilman first met Martoma through paid consultations arranged by the expert network firm. Gilman provided Martoma with nonpublic information concerning the Phase II trial starting in at least 2007. In the weeks leading up to the July announcement, Gilman held several calls with Martoma during which he provided information regarding the safety and efficacy results for the trial. On July 17–18, 2008, Gilman and Martoma had a lengthy phone call during which Gilman suggested that the drug had potential serious negative side effects.

On the morning of Sunday, July 20, 2008, Martoma indicated to a portfolio manager of the affiliated asset management company that he was no longer comfortable with the Elan investments held. Before the market opened on July 21, 2008, these portfolios held over 10.5 million Elan shares worth over $365 million, and over 7.1 million Wyeth shares, worth over $335 million, a combined position of over $700 million. On the morning of July 21, 2008, the portfolio manager began selling

---

[2]For a more extensive and vivid description of Martoma's case and his involvement with SAC Capital, see Kolhatkar (2018).

Figure A1
Chronology of Martoma's insider trading investigation and stock prices
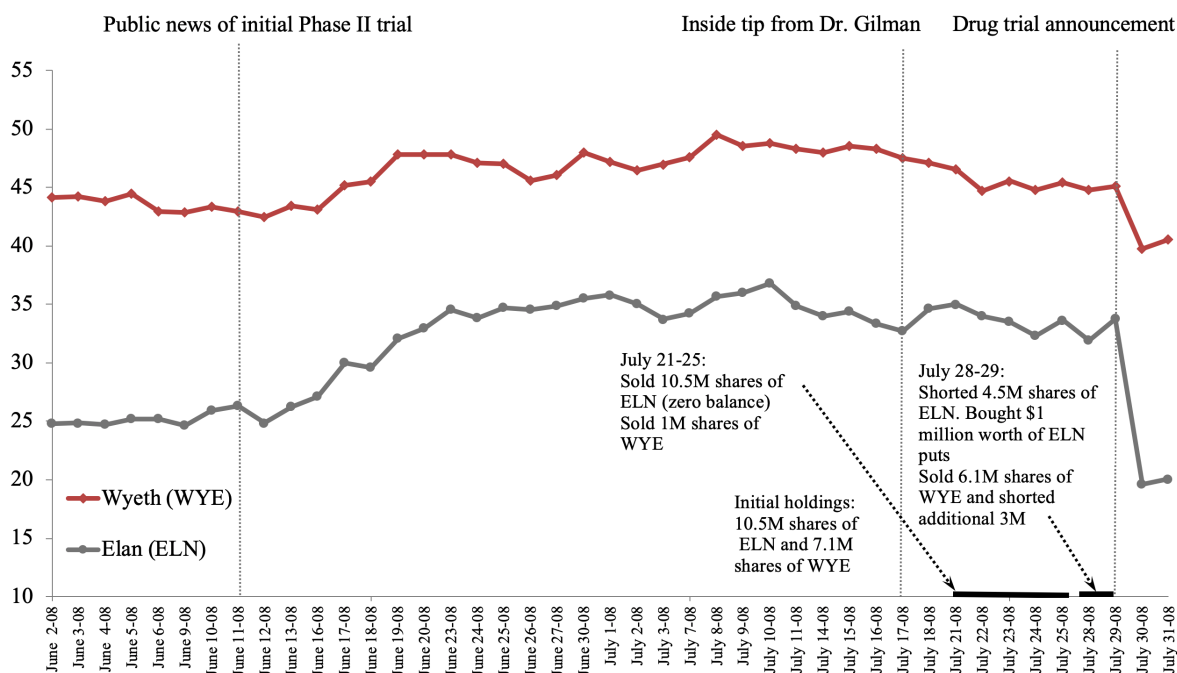

both companies' shares. Later, the manager communicated to Martoma that he had executed the sale of over 10.5 million Elan shares at an average price of $34.21 over a four-day period.

Although the investment advisers' portfolios achieved a zero balance in Elan securities by July 25, 2008, they continued to sell short Elan securities on July 28 and 29, until the public announcement. By the close of the market on July 29, 2008, both companies had a combined short position of approximately 4.5 million securities. The gross sales proceeds of Elan shares exceeded $500 million and constituted over 20% of the reported trading volume in the seven days prior to the announcement. In addition, on July 28 and July 29, Martoma and the portfolio manager purchased over $1 million worth of Elan put options with strike prices below the Elan share price on those three trading days.

Regarding Wyeth, between July 21, 2008, and July 29, 2008, both companies sold over 10.4 million shares, for gross proceeds of over $460 million, including over 6.1 million Wyeth shares, worth over $270 million, during the announcement day. As a result of these sales, they reached

a zero balance in Wyeth stock during the trading day on July 29, 2008, but continued to place short sales that day. By the close of the same day, the portfolios had a combined short position of approximately 3.3 million Wyeth shares. The trading in Wyeth securities constituted over 11% of the reported trading volume in the seven days prior to the announcement.

On July 29, 2008, after the close of the U.S. markets, Gilman presented the results of the Phase II trial at the aforementioned conference. The market reacted negatively. On July 30, 2008, Elan's shares opening price was $19.63, declining nearly 42% relative to the previous close price of $33.75. In turn, Wyeth's stock price fell from to $39.74 from $45.11, a decrease of nearly 12%. Figure A1 presents the time series of Elan and Wyeth stock prices and summarizes Martoma's trades.

As a result of the trades motivated by Martoma's conversations with Gilman on July 17, 2008, the involved parties reaped profits and avoided losses of over $276 million. At the end of 2008, Martoma received from SAC Capital a bonus of over $9.38 million, while Gilman received merely over $100,000 from the expert network firm for his consultations with Martoma and other analysts.

Following the inquiry based on the whistleblower tip, the SEC launched a formal investigation. On February 6, 2014, Martoma was found guilty of insider trading. Subsequently, on September 8, 2018, the SDNY sentenced him to nine years in prison. He was also requested to forfeit his bonus. Gilman agreed to forfeit $234,000, the amount he earned in the scheme, plus interest.

A.3 Additional Tables

Table A1
Insider Traders: Personal and Professional Background

This table reports the numbers of insider traders in our sample distributed according to age, gender, and job category. The sample period is from 1995 to 2015.

Personal background	Value
Average age traders	47.16
Median age traders	46
Median age tippers	45
Gender (% of males)	91.89
Corporate function	**Number of traders**
Employee/Low-level management	105
Mid-level management	84
Vice president	67
CEO	38
Director	32
President	32
CFO	24
Other	28
Jobs in the financial sector	
Portfolio manager/Hedge fund	59
Broker or dealer	30
Analyst	21
Trader	16
Financial Advisor	7
Other	16
Non-finance jobs	
Business owner/self employed	52
Lawyer/Attorney	42
Medical doctor / dentist	24
Accountant	14
Sales	13
Engineer /IT	12
Real estate broker	11
Other	26

B   Appendix to Section 3

This appendix includes the proof of Proposition 1 and supplemental figures.

B.1 Proof of Proposition 1

We verify that the system of equations (8) to (12) is a unique linear equilibrium by following the three-step strategy in the proof of Theorem 2 of Kyle (1985). The key differences with the latter are found in the first step.

1) Trading strategy. First, we use backward induction to find optimal informed trades based on the conjectured pricing rule. Consider the informed trader problem at time $t = 2$. The expected penalty can be written as $K(x_1, x_2) = qc(x_1^2 + x_2^2 + 2x_1x_2)$. Substituting K in equation (7), and re-arranging, the objective function can be written as:

$$\max_{x_2 \in \mathbb{R}} (v - p_1 - 2qcx_1)x_2 - \gamma_2 x_2^2,$$

where $\gamma_t := (\lambda_t + qc)$. The optimal order x_2 must satisfy the following first-order condition:

$$x_2^* = \frac{(v - p_1 - 2qcx_1)}{2\gamma_2}. \tag{1}$$

Note that, unlike in the traditional Kyle model, the optimal x_2 depends on the value of x_1 because enforcement risk creates a new intertemporal dependency. Satisfying the second order condition requires $\gamma_2 > 0$.

Using (1), we can express the value function V_2 as

$$V_2 = \mathbb{E}\left[x_2^*(v - p_1 - \lambda_2(u_2 + x_2^*))|\, v, p_1\right] - qc\left(x_1^2 + x_2^{*2} + 2x_1x_2^*\right),$$

$$\Rightarrow V_2 = \frac{(v - p_1 - 2qcx_1)^2}{4\gamma_2} - qcx_1^2. \tag{2}$$

Consider now the insider problem at $t = 1$. Using equation (2), we can re-write the program in equation (6) as

$$\max_{x_1 \in \mathbb{R}} \mathbb{E}\left[(v - p_0 - \lambda_1 y_1)x_1 + \frac{(1 - \rho)}{4\gamma_2}(v - p_1 - 2qcx_1)^2 |v\right] - qcx_1^2. \tag{3}$$

7

Expanding the term $(v - p_1 - 2qcx_1)^2$, evaluating the expectation, and dropping constant terms, we can write (3) as

$$\max_{x_1 \in \mathbb{R}} \left\{ (v - p_0) x_1 (1 - 2\theta (\gamma_1 + qc)) + \left(\theta (\gamma_1 + qc)^2 - \gamma_1 \right) x_1^2 \right\},$$

where $\theta_2 = \frac{(1-\rho)}{4\gamma_2}$. The first-order condition is

$$(v - p_0) (1 - 2\theta (\gamma_1 + qc)) = 2 \left(\gamma_1 - \theta (\gamma_1 + qc)^2 \right) x_1,$$

implying that

$$x_1^* = \frac{(v - p_0) (1 - 2 (\gamma_1 + qc) \theta)}{2 \left(\gamma_1 - (\gamma_1 + qc)^2 \theta \right)}. \tag{4}$$

Therefore, $\alpha_1 = -\beta_1 p_0$ and

$$\beta_1 = \frac{(1 - 2 (\gamma_1 + qc) \theta)}{2 \left(\gamma_1 - (\gamma_1 + qc)^2 \theta \right)}.$$

The second-order condition can be expressed as $\lambda_1 > \theta (\lambda_1 + 2qc)^2 - qc$.

To find α_2 and β_2, we combine equations (1) and (4) to obtain

$$x_2^* = \frac{1}{2\gamma_2} (v (1 - 2qc\beta_1) - p_1 + 2qc\beta_1 p_0).$$

Therefore,

$$\beta_2 = \frac{1}{2\gamma_2} (1 - 2qc\beta_1),$$

$$\alpha_2 = \frac{1}{2\gamma_2} (2qc\beta_1 p_0 - p_1).$$

2) Learning and prices. Based on the insider strategy and using a market efficiency condition, we address the market maker learning problem and derive the pricing rule. In period $t = 1$,

8

informational efficiency requires that the asset satisfy $p_1 - p_0 = \mathbb{E}\left[v - p_0 | \alpha_1 + \beta_1 v + u_1 = y_1\right]$. Given the normal distribution assumption for v and u_1, the projection theorem implies that λ_1 must be given by (10). In period $t = 2$, based on the signals y_1 and y_2, informational efficiency requires that $p_2 - p_1 = \mathbb{E}\left[v - p_1 | \alpha_2 + \beta_2 v + u_2 = y_2\right]$. Then,

$$\mathbb{E}\left(v - p_1 | y_1, y_2\right) = \frac{\beta_2 \sigma_{v|y_1}^2}{\beta_2^2 \sigma_{v|y_1}^2 + \sigma_u^2} y_2, \tag{5}$$

Using equation (5) and $\sigma_{v|y_1}^2 = \frac{\sigma_v^2 \sigma_u^2}{\beta_1^2 \sigma_v^2 + \sigma_u^2}$ yields $\lambda_2 = \frac{\beta_2 \sigma_v^2}{\left(\beta_2^2 + \beta_1^2\right)\sigma_v^2 + \sigma_u^2}$.

3) Having characterized the linear structure of trading strategies and the pricing rule in steps 1) and 2), the existence of a unique way to iterate the system backward follows from the arguments of Kyle (1985). ∎

9

B.2   Supplemental Figures
Figure B2
Equilibrium: information and legal risk

Figure B3
Comparative statics: Kyle model parameters
The baseline v, σ_u, and σ_v parameter values are as in Section 3, with $\rho = 1/2$, and $c = 1/60$. High v, σ_u, and σ_v values correspond to 15, 16.86, and 135, respectively.

C Appendix to Section 4: Supplemental Tables

Table C2
Differences Among Courts

The table reports the F-statistics for the test of joint significance of coefficients of court-fixed effects, individually for insider characteristics and sentencing outcomes. All insider characteristic are defined in Section 1. Court fixed effects are related to the court in which the settlement takes place. *Penalty* is a dollar amount of assessed penalty (in \$million). *Jail* is an indicator variable equal to one if an insider receives a jail sentence, and zero, otherwise. All other controls are defined in Table IV. ***, **, * denote 1%, 5%, and 10% level of statistical significance, respectively.

F-statistic	
Insider Characteristics	
Age	2.03
Gender	1.47
Finance	1.75
Executive	1.84
Sentencing Outcomes	
Penalty	25.46
Jail	7.77

D Appendix to Sections 5 and 6

This appendix presents a taxonomy of tests in Sections 5 and 6 and supplemental tables.

D.1   The Taxonomy of Exogenous Variation in Legal Risk

From the perspective of a risk-neutral insider, legal risk exposure is captured by the expected legal cost, which can be decomposed as follows:[3]

$$\text{prob(detection)} \times \text{prob(prosecution|detection)} \times \text{legal penalty.}$$

The following table summarizes the connection between these three components and the empirical tests in Sections 6 and 7.

Table D3
Taxonomy of Legal Risk Variation Sources

Test/Variation	Detection	Prosecution	Penalties
Section 5: time-series analyses			
Dodd-Frank			5.1
Newman ruling		5.2	
Google Trends	5.3		
Section 6: cross-sectional analyses			
SDNY-Bharara			6.1
WRP	6.2		
Lawful traders		6.3	

Our classification is based on both the institutionals of insider trading prosecution and economic rationale. Although we argue each test design best represents one aspect of legal risk, we do not claim that categories are mutually exclusive. For example, our penalty data supports the fact that the Dodd-Frank period, 2011–2013, represents a positive shock to penalties. At the same time, the WRP introduced by the same legal act increases the probability of detection. While the penalty effect is likely to affect insider traders across the board, as tested in Section 5.1, enhanced detection is more likely to affect those traders that would have otherwise eluded the regulators' radar, which is the motivation of the cross-sectional test in Section 6.2.

We also note that, unlike all other tests, the prosecution risk shocks are of *negative* sign: By narrowing the scope of illegal insider trading, the Newman ruling shock makes prosecution less likely. Similarly, traders that acted lawfully face ex ante a lower risk of prosecution.

---

[3]The stylized analytical framework in Section 3 considers $q = \text{prob(detection)} \times \text{prob(prosecution|detection)}$.

D.2 Supplemental Tables

Table D4
SEC Whistleblower Cases: Summary Statistics

We consider the insider trading trades from 2008 to 2013. We define two sets of insider trading cases: WRP=1 are cases that have been investigated by the SEC based on Whistleblower Reward Program; WRP=0 are the cases with unknown origin of investigation sampled during the sample time period.

| Characteristic/Sample	WRP=1	WRP=0
Number of Cases	47	140
Distance from news to trade	6.82	7.60
Distance from trade to event	15.48	17.46
Distance from first to last trade	7.59	6.85
Trades per firm	5.61	7.33
Trades per trader	8.29	9.92
Market capitalization (in Billions)	10.27	5.82
Reported profits (in Millions)	0.98	1.31

E Appendix to Section 7: Price Adjustment to Insider Trades

We consider a nonparametric time scale by dividing the period between T_{first} and T_{public} into 10 subperiods of equal length, and calculate for each subperiod the median cumulative stock return across events. The results are in Figure E4. By construction, the sample of cases in the figure have trading horizons of at least 10 days. Each of the first 10 bars corresponds to the trading subperiod. The rightmost bar corresponds to the median PSV value, representing the *total* amount of information. The dotted line corresponds to the ratio of the corresponding cumulative return to the PSV, as a percentage, expressing the amount of private information impounded into the price over time (100% on date $T_{\text{public}} + 1$).

Figure E4

Trades and information transmission into prices

This figure displays the process of information aggregation into prices. Trading horizons are divided into 10 subperiods. Each of the 10 leftmost (black) columns represents the cumulative return from the first trade up to the corresponding decile. The rightmost column corresponds to the median private signal value. The dotted line corresponds to the percentage ratio between each decile column and the rightmost column and reflects the proportion of private information in prices.
