EXPOSURE TO MORE FEMALE PEERS WIDENS THE GENDER GAP IN STEM PARTICIPATION

Abstract

This paper investigates how high school gender composition affects students' participation in STEM at college. Using Danish administrative data, we exploit idiosyncratic within-school variation in gender composition. We find that having a larger proportion of female peers reduces women's probability of enrolling in and graduating from STEM programs. Men's STEM participation increases with more female peers present. In the long run, women exposed to more female peers are less likely to work in STEM occupations, earn less, and have more children. Our findings show that the school peer environment has lasting effects on occupational sorting, the gender wage gap, and fertility.

I. Introduction

In most OECD countries, women attain more education than men. Despite this reversal of the gender gap in education, large gender differences in the choice of study field persist. Only 28 percent of college students in Science, Technology, Engineering, and Mathematics (STEM) studies are female (OECD, 2016). As gender differences in ability do not seem to explain these differences (Kahn and Ginther, 2017), we currently know little about why women remain underrepresented in STEM fields. It is important to improve our understanding of the origins of gender differences in study choices due to the potential consequences for both the individual and society. On an individual level, women with high math and science ability who do not participate in STEM forfeit higher lifetime earnings. On a societal level, when fewer women are part of the STEM workforce, society may be less innovative and thereby have worse long-run economic growth.

In this paper, we investigate how gender composition in high school affects men's and women's decisions to choose STEM fields in higher education. High school peers represent a central aspect of teenagers' social environment given that they interact daily for several years. During this time, students face one of their most crucial life choices. Therefore, peers may represent an important social force shaping specialization decisions. To investigate whether gender composition in high school affects the gender gap in STEM participation, we use Danish register data on all students entering the math track in high school between 1980 and 1994. The key advantage of this data set, in addition to its rich information on individuals' education and labor market outcomes, is that we can follow the entire student population over a period of 20 years after they entered high school. This allows us to identify the direct, delayed, and long-run consequences of high school peers.

Our strategy to identify the causal impact of gender composition on STEM choice builds on two empirical approaches that differ in their key identifying assumptions and interpretation of

results. The first empirical approach exploits idiosyncratic cohort variation in the proportion of female students *within schools* across cohorts after taking out school fixed effects, cohort fixed effects, and school-specific time trends.¹ The second empirical approach extends this model by including cohort-by-school fixed effects, thereby examining whether the proportion of female peers *differentially* affects men and women *within the same school-cohort*. This identification strategy thus answers whether the gender gap in STEM choice grows or shrinks as the gender composition changes.²

The key identifying assumption for our first strategy is that year-to-year variations in the proportion of female students are exogenous to factors affecting STEM choice, conditional on school fixed effects, cohort fixed effects, and school-specific time trends. To assess the credibility of this identifying assumption, we conduct an extensive set of balancing checks, testing whether changes in gender composition are associated with student characteristics. Using a large set of student background characteristics from the register data, we show that gender composition does not systematically relate to the characteristics of students selecting into the specific school cohort, conditional on school and cohort fixed effects.³ While this balancing test provides strong support for our key identifying assumption, it remains theoretically possible that students sort into schools based on factors correlated with STEM choice that are both time variant and unobservable in the register data. Although it is difficult to think of mechanisms that would create these unobservable

¹ This identification strategy is similar to Anelli and Peri (2019), Hill (2017), Hoxby (2000), and Lavy and Schlosser (2011), who exploit idiosyncratic variation in the proportion of female students within schools.

² This identification strategy is used by Merlino, Steinhardt, and Wren-Lewis (forthcoming) to test whether the peer composition in high school affects the probability of interracial romantic relationships. Our strategy is analogous to the literature that estimates differences between siblings, including sibling fixed effects (instead of cohort-by-school fixed effects), by, for instance, considering how sisters (women) and brothers (men) are differentially affected by the childhood family environment (high school peer composition) (Brenøe and Lundberg, 2017, Autor et. al, forthcoming).

³ We also test and reject the possibility that the proportion of female students enrolling in a given school is autocorrelated over time. Put differently, we find no evidence that the proportion of female students in year $t-1$ predicts the proportion female peers in year t .

time-variant school selection patterns, our second empirical approach addresses this concern. The inclusion of fixed effects for each cohort-by-school cell alleviates remaining potential concerns, as we can control for the exact level at which selection based on *time variant* and *unobservable* characteristics would take place.⁴ Both of our empirical approaches yield qualitatively similar results.

Our results show that women exposed to a higher proportion of female peers become less likely to enroll in STEM fields and more likely to enter health-related studies in college. Men are overall less affected, but also behave more gender-stereotypically when more female peers are present: they become more likely to enroll in STEM studies and less likely to enter health-related studies. These peer effects in field of study choice are statistically and economically significant. A 10 percentage point increase in the proportion of female high school peers lowers women's probability of enrolling in STEM studies by 1.4 percentage points—which is equivalent to a 6.4 percent decrease from the baseline. For men, a similar change in the gender composition raises STEM enrollment by 0.9 percentage points (2.4 percent). These peer effects exacerbate gender differences not only in STEM enrollment but also translate into an increased gender gap in STEM-degree completion. In our most conservative model, which includes cohort-by-schools fixed effects, we find that 10 percentage points more high school female peers increase the gender gap in STEM-degree completion by 2 percentage points, corresponding to a 17 percent increase.

We shed some light on possible mechanisms behind this finding by studying how peer gender affects student performance, measured as high school grade point average (GPA). Since high-achieving students are generally more likely to enter STEM fields and it has been shown that

⁴ It is important to note that results from regressions including cohort-by-school fixed effects no longer identify whether an increase in the proportion of female peers affects the levels of STEM enrollment for men and women, but instead identify gender differences in response to changes of the peer environment.

peers affect performance in high school (e.g. Hoxby, 2000; Lavy and Schlosser, 2011), one possible mechanism is that the gender composition affects men's and women's preparedness for STEM studies. We find evidence in support of this mechanism: having more female peers alters the gender gap in high school GPA in favor of men, which may give women—who consider their comparative advantage—reason to believe that they are less prepared for college studies in STEM. When considering heterogeneous effects by parental background, we provide two pieces of evidence that suggest that information about college in general and STEM studies in particular can counter peer influences to some degree. First, students with college-educated parents are less affected by peers. Second, and more strikingly, the gender peer composition does not influence women with STEM-educated mothers, i.e. women who have a salient female role model at home.

Our long-run results on labor market trajectories show that the peer effects in study choice lead women and men to systematically different career paths. Not only are women who are exposed to more female high school peers less likely to choose STEM studies, they are also less likely to work in STEM occupations, and they have lower earnings at age 36. A 10 percentage point increase in the proportion of female high school peers lowers women's probability of working in STEM occupations by 4 percent and increases the gender wage gap by 5 percent. These results imply that high school peers and their influence on college major choice have lasting and economically significant consequences for occupational segregation and earnings.

Finally, we study how peers affect individuals' fertility outcomes and find that women exposed to more female peers have more children by age 36. For the interpretation of this effect, it is relevant to note that the peer gender composition may affect fertility preferences either directly or indirectly. An indirect impact could arise, for instance, if STEM careers are associated with less family-friendly work environments. Although we ultimately cannot disentangle whether reduced fertility indeed is due to entering STEM fields, it is possible that it might be harder to combine

having children with work obligations in STEM occupations. Another important possibility that might help explain the increase in the gender wage gap when having more female peers is that having (more) children reduces earnings for women (Kleven et al. 2018; Lundborg et al. 2017). In such case, lower female earnings should not be attributed to staying out of STEM fields per se, but would instead be a consequence of the "career cost of children" (Adda et. al., 2017).⁵

In the existing literature, only a handful of related studies investigate how the gender of peers in high school influences educational choices.⁶ Lavy and Schlosser (2011) find that both male and female students perform better and take more science courses in high school when exposed to more female peers. In contrast to this, we find that women become less likely to enter subsequent STEM studies and that only men perform better in high school with more female peers present. While Lavy and Schlosser (2011) provide intriguing evidence on the underlying mechanisms, it is not possible to study long-run effects on study choice, occupational sorting, fertility, or earnings in their setting.

Closely related to our work, Anelli and Peri (2019) show that the gender composition in high school has an effect on men's, but not on women's, study choice in college. While Anelli and Peri leverage random assignment of students to classes for identification, we use idiosyncratic cohort variation in female peers within schools. Anelli and Peri find that men attending high school classes with over 80 percent male peers are more likely to enroll in predominantly male college majors.⁷ Contrary to our findings, these effects do not persist into actual degree completion or affect

⁵ Related to this point, if peers shape individuals' preferences for children—even before those children are born—men and women may choose more family-friendly careers outside of STEM that can facilitate their family planning. In this case, the choice of study field might reflect the changed fertility preferences.

⁶ Starting with Hoxby (2000), a different but related strand of literature investigates how gender composition affects student performance. For important studies on the impact of peer gender on performance, see Whitmore (2005), Lavy and Schlosser (2011), De Giorgi, Pellizzari, and Woolston (2012), Oosterbeek and Ewijk (2014) as well as Hill (2015).

⁷ In contrast to Anelli and Peri (2019) who consider enrollment in and graduation from programs in Engineering, Economics, and Business, we study whether students choose any STEM field, which also includes Science, Technology, and Mathematics, and follow each student for 20 years after high school entry.

earnings.⁸ While Anelli and Peri focus on the effect of being in a very male-dominated environment—at least 80 percent male peers—we consider a continuous measure of female peers and thus identify effects at a different margin of the gender composition.

At the college level, Hill (2017) presents suggestive evidence that women exposed to a university cohort with more female peers have a lower probability of majoring in STEM fields. Similarly, Zölitz and Feld (2019) show that women become less likely to major in male-dominated subfields when they are randomly assigned to university sections containing more female peers. On the contrary, Schneeweis and Zweimüller (2012) show that a larger share of female peers in lower secondary vocational school increases girls' propensity to choose male-dominated school types. Based on the existing literature, which presents mixed evidence from a variety of different settings, it is not clear how gender composition affects specialization decisions.⁹ Finally, our paper also relates to a different strand of the literature studying how the social environment shapes fertility decisions (Balbo and Barban, 2014; Ciliberto et al. 2016; Kuziemko, 2006; and Brenøe 2018), which previously has not been examined by the gender peer effects literature.

This paper contributes to the literature in three important ways. First, we are the first to document that gender composition in high school affects STEM participation in college. Second, we provide previously undocumented comprehensive evidence on the long-run occupational consequences of high school peers. Our ability to follow students in the Danish administrative data over the course of 20 years after high school entry distinguishes this study from existing work that mostly studies the short- or medium-run impact of peers. Third, and more broadly, this paper

⁸ While Anelli and Peri (2019) observe only earnings in the year 2005 for a part of their sample, we utilize panel data on earnings and employment and thereby follow the earnings trajectory at an annual level through age 36 for all individuals in our sample.

⁹ The related literature on the impact of single-sex education also provides mixed results. While Jackson (2016) finds that single-sex secondary schools cause girls to take fewer math and science courses, other studies find no impact (Sohn, 2016) or a positive effect (Lee et al. (2014) and studies cited therein).

contributes to a better understanding of the origins of gender differences in educational choices and labor market outcomes. While we do not offer a universal explanation for women’s underrepresentation in STEM, we identify one relevant factor that contributes to this gap. To the extent that our results for Denmark replicate in other environments, this paper shows that the gender composition of high school peers represents an important aspect of the social environment that shapes individuals’ preferences for field of study, occupation, and fertility.

II. Institutional Background and Data

In this study, we use Danish administrative data covering the entire population of first-year high school students enrolled in the math track from 1980 through 1994. This group of students represents the student population for whom the choice of specialization within STEM fields in college is highly relevant. The key advantage of our data set is that it contains rich background information and allows us to follow individuals over the course of 20 years after high school entry. We link the administrative data on high school students to annual data on educational enrollment and degree completion, which also contain detailed information on the type, level, and field of education, as well as labor market outcomes up to 20 years after entering high school. In the rest of this section, we introduce the institutional setting, describe the estimation sample, and present summary statistics on the key variables of the analysis.

A. Institutional Background

Children in Denmark enter primary school the year they turn seven years old and are required to

attend school through grade 9.¹⁰ Attendance at grade 10, which is a formal continuation of primary school, is optional. In their final year of primary school, students apply for secondary school. When applying for secondary education, students can choose between academic high schools, which take three years, or vocational programs, which typically take four years.¹¹ The general academic high school, which represents the most popular type of academic high school, has two tracks: math and language.¹² The curriculum for the two tracks is significantly different, with the math track preparing students for tertiary education within STEM fields or more quantitative-oriented social science programs. In contrast, the language track prepares students for tertiary education within humanities or less-quantitative oriented social science programs and does not offer students the courses required by most university STEM programs. Academic high schools normally offer both tracks; approximately two-thirds of the students attend the math track and the remaining one-third attend the language track, which is typically female-dominated.¹³ Students in both tracks share the same building and social events, such as Friday bars or sport competitions. The two tracks typically will not have any classes together, although it is possible that some students take an elective course within the other track, such as a second foreign language. Therefore, students within the same track are likely to be the most relevant peer group for subsequent educational decisions.¹⁴

In the high school application process, students specify their first, second, and third choice of a combination of specific high schools *and* track. Students are qualified for high school admission if they have completed at least nine years of education with satisfactory results and if

¹⁰ For the cohorts we study, it was not mandatory to attend a kindergarten class (grade 0), but most children did so.

¹¹ Academic high schools fall broadly into three branches: general, commercial (HHX), and technical (HTX).

¹² During the period we study, about 18 percent of each birth cohort enrolled in the math track, and about 45 percent of students within the math track are female. Both the share of math-track students and the share of women within the math track were relatively constant over the period our estimation sample covers.

¹³ Approximately 80 percent of language track students are female. All schools are mixed sex.

¹⁴ Table 6 considers different definitions of the relevant peer group.

teachers confirm their qualification.¹⁵ All applicants qualified according to these criteria are guaranteed admission to a high school in their county of residence, and admission does not depend on academic achievement in primary school. If there is insufficient capacity at all three of the student's preferred schools, the allocation committee in their home county admits them to another school after considering commuting time.¹⁶ Schools experiencing capacity problems are concentrated in metropolitan areas. Students submit the application in the winter of their last year in primary school and only learn of the gender composition in their actual high school track cohort on the first day in high school in August— six months later.

After high school completion, many students take one or two gap years before entering college.¹⁷ During the period of study, students chose a specialization within their track at the end of the first year in high school. Before high school reforms in 1988, all high schools were required to offer the same few specialization packages (for details, see Joensen and Nielsen, 2016). After the reforms, high schools were still required to offer certain courses (including courses required for all types of university programs) but had more leeway to offer a wider spectrum of courses, and students had more options to combine different types of courses. Therefore, a certain gender composition within a school would not directly have affected the course availability for students.

In the college application process, students apply for a specific field of study and a specific institution and can indicate up to eight institution-specific study programs. A diploma from an academic high school is required for admission. Admission depends on high school GPA; however, most STEM programs have no or very low GPA cutoffs and almost all eligible students who apply are admitted. While GPA does not restrict students' STEM study choice, certain high school

¹⁵ If these conditions are not met, students can still qualify for school admission if they pass an entrance exam.

¹⁶ According to conversations with school principals active during our observation period, admission committees did not consider the gender of applicants during the admission process.

¹⁷ We define college as professional and academic tertiary education.

courses, such as Advanced Mathematics and Intermediate Physics and Chemistry, are prerequisites for STEM college majors. In other words, to be eligible to enter STEM college studies, a math track high school diploma is almost a necessity.¹⁸ Throughout this paper, we therefore focus on students within the high school math track—students for whom entering STEM fields in college represent a relevant career option. Among students within the math track, 30 percent later decide to enroll in a STEM program; students from other high school tracks rarely choose STEM studies.¹⁹ Math track students thus represent the most relevant margin for increasing women’s STEM participation.

B. Estimation Sample

We exclude students with missing values for gender and age (0.8 percent of students) and students who were not between 14 and 19 years old when entering the general high school (less than 0.01 percent). We further restrict the estimation sample to schools in which at least 95 percent of students in a given cohort are 14–19 years old and exclude schools with very small cohort sizes of less than 10 students in a given year (6.1 percent of students). We apply these restrictions to exclude schools that mainly offer evening education or single courses; these schools target older part-time students who are, in many cases, working at the same time. Finally, we restrict the sample to schools that have been in existence and have admitted students for at least four consecutive years (excluding 0.6 percent of students). None of these data restrictions qualitatively change the results.²⁰

¹⁸ However, it is possible to take extra courses after high school graduation to meet the entry criteria.

¹⁹ For comparison, only 4.6 percent of STEM college graduates attended the high school language track.

²⁰ Results are available upon request.

C. Summary Statistics

Table 1 provides an overview of the summary statistics. Our estimation sample consists of 182,211 students attending 127 different schools over a period of 15 years, resulting in a total of 1,877 school-cohort observations. Forty-five percent of the students are female, and the average cohort size in the math track is 108 students.

[Table 1 here]

Panel A in Table 1 shows the student outcomes we consider in this paper. The primary outcomes of interest are indicators for whether the student enrolls in a STEM study field and whether their college degree is within STEM fields at the college level or higher.²¹ To classify STEM study programs, we follow the International Standard Classification of Education (ISCED) classification system (UNESCO Institute for Statistics, 2012). STEM degrees are thus studies within the following ISCED fields: Natural Sciences, Mathematics, and Statistics (ISCED-05), Information and Communication Technologies (ISCED-06), and Engineering, Manufacturing, and Construction (ISCED-07). To examine which fields within STEM drive the effects, we also split STEM into four subfields: 1) Biology, 2) Math and Physics, 3) ICT and Engineering, and 4) Manufacturing and Construction. Additionally, we consider the probability of completing the highest degree within Health Sciences (ISCED-091), Education (ISCED-01), Arts/Humanities (ISCED-02), Social Sciences (ISCED-031), and Business/Law (ISCED-04).

From the total sample, 79 percent of all students enroll in college after high school. Table 1 shows that only 21 percent of female and 38 percent of male high school students subsequently enroll in STEM studies. This gender gap persists in STEM completion rates: while only 14 percent

²¹ Throughout the paper, we use the field of the highest obtained degree to construct measures of STEM completion. The enrollment variables are indicators for the student's ever having been enrolled in the respective study at the college level or higher. If we instead consider the field of first or last enrollment, we find very similar results throughout.

of women graduate with a STEM degree, 25 percent of men do so. Labor market outcomes show that 20 years after high school entry, 11 percent of women and 26 percent of men work in a STEM occupation.²²

Panel B in Table 1 provides an overview of the student demographic and parental background characteristics we use in the regression analysis as controls, and Panel C shows school-level variables. The key peer variable of interest is the proportion of female peers at the time of high school entry, which we construct at the cohort-school-track level excluding the individual himself or herself. As less than one percent of students change to another high school or track, this group of peers represents the social group in which students interact over a three-year period. Students are, on average, exposed to 45 percent female peers. A one standard deviation change in the proportion of female peers is equivalent to 7.0 percentage points.

Figure 1 shows the raw correlations between the proportion of female peers and the probability of completing a STEM degree. For women, a higher proportion of female peers is correlated with a lower probability of obtaining a STEM degree. For men, on the contrary, we observe a positive correlation between the proportion of female peers and STEM degree completion. These raw associations suggest a fairly linear relationship. Although these correlations are purely descriptive, they foreshadow the results of our regression analysis.

[Figure 1 here]

²² We use the Danish version of the International Standard Classification of Occupations (DISCO) and construct an indicator for working in STEM if the individual works in a high-skilled occupation within STEM for at least half the years observed, 11–15 and 16–20 years after high school entry, respectively. All results remain qualitatively the same when using indicators for whether the mode occupation is within STEM for the considered periods.

III. Empirical Strategy

The fundamental threat to identification of peer effects arises from student sorting at various institutional levels. Parents select into neighborhoods, students select into schools, and within schools, students may select into classrooms or be assigned to tracks. As students are typically not assigned to schools at random, the existing peer effects studies try to overcome this identification problem by exploiting natural variation in cohort composition within a given school across time (Bifulco, Fletcher, and Ross 2011; Carrell and Hoekstra, 2010; Carrell, Hoekstra, and Kuka 2018; Hanushek et al. 2003; Hoxby, 2000; Hoxby and Weingarth, 2005; Lefgren, 2004; Vigdor and Nechyba, 2006). Although this identification strategy addresses the issue of endogenous, time-constant student sorting into schools, it is vulnerable to school-specific (dynamic) time trends that may alter both the peer composition and the outcome of interest. More recent peer effects studies respond to this concern with the inclusion of school-specific time trends—linear, quadratic, and cubic (Hill, 2017; Lavy and Schlosser, 2011; Lavy, Schlosser, and Paserman 2012; Schneeweis and Zweimueller, 2012). For identification, these studies exploit the deviation in peer composition from its long-term time trend within a school. This approach has the advantage of controlling for unobserved factors correlated with time trends in school composition that may confound peer effects in schools.

Our first empirical approach is similar to the approach in the literature discussed in the previous paragraph, and shares the key identifying assumption that the variation in the peer composition is exogenous after taking out school fixed effects, cohort fixed effects, and school-specific time trends. In our second empirical approach, we estimate an even more restrictive model by including fixed effects for each cohort-by-school cell, thereby alleviating all remaining potential concerns regarding selection. In the following, we describe our empirical model, our two identification strategies, and the underlying assumptions in more detail.

A. Empirical model

Our main empirical model is:

$$Y_{isc} = \beta_1 Female_i \times PropFemalePeers_{isc} + \beta_2 Male_i \times PropFemalePeers_{isc} + \beta_3 Female_i + C_{isc}\gamma' + e_{isc}, \quad (1)$$

where Y_{isc} is the outcome of student i attending school s in cohort c . The main outcomes we consider are STEM participation, the individuals' earnings percentile by age and birth cohort, and fertility. In our data, each individual represents one observation. The treatment variable of interest is $PropFemalePeers_{isc}$, which represents the proportion of female peers individual i is exposed to in their school s and cohort c . To investigate heterogeneity by gender, we interact the proportion of female peers with the indicator variables $Female_i$ and $Male_i$ that refer to the students' own gender.

β_1 thus captures to what degree women's study choices and labor market outcomes are affected by the peer gender composition in their high school, and β_2 captures the equivalent impact for men. β_3 captures the gender gap in outcomes conditional on controls. C_{isc} represents a vector of school and cohort fixed effects as well as individual and peer characteristics that we gradually add when estimating Equation (1). The inclusion of high school fixed effects accounts for time-invariant endogenous sorting into schools, and cohort fixed effects control for confounding factors at the national level, affecting all students in a given cohort. In order to account for unobserved time-variant school characteristics correlated both with changes in the proportion of female peers and educational choices for students within the same schools, we add school-specific linear, quadratic, and cubic time trends to the vector C_{isc} .

In our more conservative models, the vector C_{isc} includes the following additional student

and peer average characteristics, which do not significantly alter our estimates: six indicator variables for mother's and father's highest educational degree and 18 indicators for their field of education;²³ indicators for first- and second-generation immigrant; a "traditional family" indicator that equals one if the student lives with both parents at age 10; dummies for student age at the time of high school start; mother's age at birth and its squared term; an indicator for having a young mother (< 22 years at birth); an indicator for whether the child is firstborn; family size and its squared term; and a dummy for whether the individual is adopted.²⁴ Additionally, we control for up to third-degree polynomials of cohort size, as peer composition may potentially be correlated with cohort size (Epple and Romano, 2011).²⁵ Finally, the vector includes the proportion of female students in the language track in the same high school cohort and controls for the high school curriculum experiment that took place in Denmark in the 1980s (for more details regarding the experiment, see Joensen and Nielsen, 2016). The main purpose of including this large vector of control variables is to test how sensitive our results are to the inclusion of these variables. In the spirit of Altonji, Elder, and Taber (2005), changes in the coefficients of interest that result from including controls may inform us about the degree to which omitted unobservable factors may affect our results. To allow students' outcomes to correlate within their group of peers, we cluster the standard errors, e_{isc} , at the school-cohort level.²⁶

²³ For each parent, we include nine dummies indicating whether their highest education is within ISCED fields 1–9.

²⁴ As individual controls, we additionally always control for dummies indicating the number of years after high school entry the individual was last observed in the education registry for our education models and dummies for the number of years observed within the given period for labor market outcomes. The inclusion of these controls reduces measurement errors given that the annual data do not record individuals living abroad.

²⁵ Moreover, we include indicators for whether the school experiences a change of more than 30 students or more than 50 percent in the cohort size compared to the previous cohort and up to two period lags of these variables. Given that a high school degree takes three years, we include these two-year lags to account for the possibility that a student's outcome was affected despite the fact that the inflow did not happen in their cohort. We furthermore control for the number of students from the cohort that are not in the age range of 14–19 years and for the number of students in the cohort that have missing gender and age information. Reasons for missing information on gender or age include that the person does not live in Denmark but attends a Danish school (e.g. lives close to the Danish-German border) or that the person resides in the country on diplomat visa. None of these included control variables qualitatively change our results.

²⁶ Angrist (2014) shows that with chance variation in peer groups, measurement error can bias peer effects estimates.

The key identifying assumption for our first approach to yield causal estimates of β_1 and β_2 in Equation (1) is that no omitted variable exists that fulfills *all* of the following four requirements:

- (1) time-variant and school specific;
- (2) not captured by school-specific time trends;
- (3) correlated with both the peer composition and the outcome of interest; and
- (4) not included in the extensive set of individual- and peer-level control variables observed in the administrative data sets.

While it is difficult to think of any plausible mechanism that would create a violation of this type, the existence of such factors remains possible. To assess the credibility that such factors do not exist, we conduct an extensive set of balancing checks in Section IV in which we test whether the peer composition in a school-cohort is systematically related to a large vector of high-quality measures of student background characteristics observable in the register data. Although these balancing tests strongly support our key identifying assumption, we also provide results from a second empirical approach. Our second approach addresses the possibility of identification problems arising from unobservable, time-variant, and school-specific omitted variables not captured by school-specific time trends that may be correlated with both the peer composition and the outcome of interest.

In our second empirical approach, we extend Equation (1) by including an additional set of fixed effects for each cohort-by-school cell. The inclusion of these cohort-by-school fixed effects alleviates potential remaining concerns, as we control for the exact level at which selection based

Feld and Zölitz (2017) study this issue in more depth and show that classical measurement error can lead to overestimation of peer effects. Because we observe the students' gender in administrative registries, gender is arguably measured without error and our estimates should thus be free from upward bias arising from measurement error.

on *time variant* and *unobservable* characteristics would take place. Importantly, estimates from this type of model no longer identify whether an increase in the proportion of female peers will affect the overall number of women and men who choose a STEM program, but instead identify a gender difference in the response to changes in the peer environment. These estimates thus answer whether the proportion of female high school peers affects gender gaps in STEM participation and earnings.

IV. Balancing tests

To assess the plausibility of our key identifying assumption that *time variant* and *unobservable* factors are not driving our results, we test whether we observe systematic selection based on a wide range of observable student characteristics. Our key identifying assumption would be violated if for example, women select into a specific school based on the expectation of a higher or lower proportion of female peers within that school-cohort. In our first balancing test, we test whether students' own gender is correlated with the proportion of female peers, conditional on cohort and school fixed effects. This test closely follows the randomization check proposed by Guryan, Kroft, and Notowidigdo (2009) and controls for the school-level leave-out mean of the proportion of female peers across cohorts within the school to account for the mechanical relationship between own gender and peer gender. Table 2 shows that the proportion of female high school peers is not systematically related to students' own gender. The point estimate is precisely estimated and not distinguishable from zero. The inclusion of individual and school level controls as well as up to cubic time trends in Columns (2)–(5) does not significantly alter the point estimate.

[Table 2 here]

While Table 2 rejects sorting based on gender, it may still be possible that students sort into

schools with a high proportion of female peers based on characteristics other than gender. The availability of a large set of high-quality measures of student background characteristics in the Danish administrative registries—typically not observable in other studies—allows us to rigorously test for this possibility.

In our next balancing test, we determine in how many cases student characteristics are significantly correlated with the proportion of female peers. Table 3 summarizes the significance of the point estimates from a total of 190 separate bivariate regressions, which test whether the proportion of female peers is related to student characteristics conditional on cohort and school fixed effects. Each column presents the results for a different set of control variables and school-specific time trends. Appendix Table A1 shows the full balancing test with all 190 coefficients. As expected when running a large number of regressions testing multiple hypotheses, some coefficients are statistically significant. In the absence of systematic sorting, we would expect 10 percent of coefficients to be statistically significant at the 10 percent significance level, 5 percent at the 5 percent level, and 1 percent at the 1 percent level simply due to chance. The share of significant coefficients is close to or below the respective expectation for all three significance levels. Table 3 shows that 1.1 percent of the estimates are significant at the 1 percent level, 2.1 percent are significant at the 5 percent level, and 8.9 percent are statistically significant at the 10 percent level. These balancing tests suggest that the proportion of female peers is as good as random and provide strong support for our key identification assumption. Without systematic cohort and school-specific sorting on this large set of observables, it appears highly unlikely that *unobservable time variant* factors create unobserved sorting patterns.

[Table 3 here]

Next, we test whether the proportion of female peers enrolling at a given school is autocorrelated over time. We do this by running 127 separate regressions that separately test, for each individual school, whether the proportion of female students at time t is correlated with the proportion of female peers that enrolled in $t-1$. Although such school-level autocorrelation would not impose a threat to our identification strategy as it would be captured by the included school-specific time trends, the existence of such school-specific time dynamics may point to the existence of other unobservable time-variant confounders. Table 4 provides a summary of this exercise and reports the proportion of schools for which we find significant autocorrelation in the proportion of female students. For all significance levels, the share of schools for which the lag of female peers significantly predicts the proportion of female peers is close to what we would expect in the absence of autocorrelation. Across all models, 0.98 percent of the school-level regressions are significant at the 1 percent level, 3.35 percent are significant at the 5 percent level, and 8.86 percent are significant at the 10 percent level. Thus, we find no evidence that the proportion of female students enrolling in a given school is autocorrelated over time.

[Table 4 here]

As another randomization check, we inspect whether the variation in the proportion of female peers, which we empirically exploit in this paper, is consistent with variation that we would expect with natural random fluctuations. Figure 2 plots the proportion of female peers at the school level after residualizing on cohort and school fixed effects and school-specific linear time trends. Figure 2 shows that these deviations in the proportion of female peers closely follow the normal distribution, which we plot for comparison. The shape of the distribution further supports the idea that the proportion of female peers is as good as random, conditional on the included controls.

[Figure 2 here]

As a final randomization check, we test whether the proportion of female peers in the math track correlates with the proportion of female peers in the language track within a given school. If the year-to-year fluctuations are indeed random, we would not expect the share of female peers to be correlated across tracks. Table 5 shows estimation results for the correlation between the proportion of female peers in the math and language tracks within schools. Reassuringly, we do not find any correlation between the female peer shares in the two tracks, independent of the set of included control variables.

[Table 5 here]

In sum, the extensive set of balancing checks in this section provides strong support for our key identifying assumption. The evidence shown in Table 2, Table 3, Table 4, Table 5, and Figure 2 suggests that the proportion of female peers is as good as random, conditional on cohort and school fixed effects.

V. Results

A. Participation in STEM College Education

Table 6 shows estimates of how the gender peer composition affects STEM enrollment (Panel A) and completion (Panel B). Because it is not obvious how to define the set of students that serve as relevant peers, we start by providing estimation results for three different definitions of school

peers, while keeping the sample of students fixed to those attending the math track. Column (1) considers the gender peer composition in the math track only, Column (2) considers the language track only, Column (3) includes both measures simultaneously, and Column (4) considers the gender composition in the entire high school cohort regardless of the attended track. Overall, the estimates show that a higher proportion of female peers—independent of how we define the relevant group of peers—lowers women’s probability of enrolling in and graduating from STEM college programs, while the opposite is true for men. Peers in the language track, however, have a weaker influence on women’s choices. For the remainder of this paper, we will focus on peers in the math track who arguably represent the peer group that math track students interact with the most.

[Table 6 here]

Table 7 shows estimates of how the peer composition affects STEM enrollment (Panel A) and STEM degree completion (Panel B) with different sets of controls.²⁷ Column (1) shows the most basic model, which includes only the proportion of female peers, student gender, and the interaction between these variables. In Columns (2)–(6), we gradually include additional fixed effects, time trends, and individual level controls. The specification in Column (6) includes school fixed effects, cohort fixed effects, a large set of peer- and student-level control variables, as well as linear, quadratic, and cubic school-specific time trends. Columns (2)–(6) show that the magnitude of the estimates is not particularly sensitive to the exact set of included fixed effects, controls, or time trends. Column (7) shows estimates from our most restrictive specification, which

²⁷ We tested whether the gender composition of peers affects the probability of dropping out of high school and the probability of enrolling in or completing college. As shown in Appendix Table A2, there is no effect.

includes cohort-by-school fixed effects and shows the impact of peers on the gender gap in STEM participation.

[Table 7 here]

The results in Table 7 show that women exposed to a higher proportion of female peers become less likely to enroll in and graduate from STEM college programs. Men’s choices also become more gender-stereotypical: they are more likely to enroll in and complete STEM studies when they have a larger share of female high school peers. In our preferred specification in Column (4), a 10 percentage point increase in the proportion of female high school peers lowers women’s probability of enrolling in STEM by 1.4 percentage points, corresponding to a decrease of 6.4 percent relative to the baseline. For men, we find that a similar change in the gender composition raises STEM enrollment by 0.9 percentage points—a 2.4 percent change from the baseline.²⁸

Column (7) shows our most restrictive model, which includes cohort-by-school fixed effects. We find that 10 percentage points more female peers in a high school cohort increases the gender gap in STEM enrollment by 2.3 percentage points—which is equivalent to a 14 percent increase of the gender gap. Because we include cohort-by-school fixed effects in the model, the coefficient in Column (7) identifies a change in the gender gap in STEM completion and not an absolute effect. Importantly, the effect size we identify is close to the difference between the coefficients of male and female students in the less restrictive models in Columns (1)–(6), which increases our confidence in the estimates obtained from the models without cohort-by-school fixed

²⁸ In addition to the linear-in-shares models shown in Table 7, we have also estimated non-linear peer effects using six bins for the proportion of female peers. In this analysis, we find relatively linear effects over the range of support that we have in the data (Figure A1 and Figure A2).

effects.²⁹ Consequently, our estimate identified from within-cohort variation implies that exposure to more female peers within a given school cohort substantially increases gender differences in STEM choice and leads to more gender-stereotypical enrollment decisions.

Do high school peers only affect enrollment decisions or do they have lasting effects on study completion as well? The distinction between study enrollment and completion is potentially important as Anelli and Peri (2019) find that gender peer effects in high school affect men's initial study enrollment, but have no impact on study completion or labor market outcomes. We therefore next shed light on the persistence of effects by considering the impact on the probability of STEM graduation.

Panel B in Table 7 shows that the peer effects in the field of enrollment persist into actual degree completion rates. In our setting, peer effects in study enrollment are not offset by changes of college major or college dropout. Women exposed to more female peers in high school are significantly less likely to graduate with a college STEM major. A 10 percentage point increase in the proportion of female peers lowers women's STEM graduation probability by 1.0 percentage points—a 7 percent decrease from the baseline (Column 4). The same change raises men's probability of graduating from a STEM field by 0.9 percentage points, which is equivalent to a 3.6 percent increase from the baseline. Again, the point estimates of interest in Columns (2)–(6) are very similar across models and are insensitive to the exact set of included fixed effects and time trends. Column (7) in Panel B confirms that these results hold when including cohort-by-school fixed effects. Gender differences also remain present in graduation rates when we exploit whether the gender composition among peers differentially affects men and women within the same school-cohort. Column (7) shows that 10 percentage points more female peers increase the gender gap in

²⁹ To see this, compare the effect size of -0.233 in Column (7) with the estimate of -0.226 (-0.135 -0.091) in Column (4).

STEM completion by 2 percentage points, corresponding to 17 percent.³⁰

Given the low baseline rates for women's STEM enrollment and graduation, the size of the peer effects we document in Table 7 are economically significant. Taken together, we find that a higher share of female peers makes both men's and women's initial choice of study field and field of graduation more gender-stereotypical.

How does the size of these peer effects compare to other factors shaping students' STEM choices? A 10 percentage point increase in female peers affects women's probability of entering STEM approximately the same as a 10 percentage point increase in the share of female professors for high-math-ability women (Carrell and Hoekstra (2010)). Our effect is approximately half the size of the impact of a one standard deviation increase in peer ability documented in Fischer (2017), which shows that exposure to high-ability peers lowers women's probability of completing a STEM degree. The magnitude of our effect is also fairly close to Zölitz and Feld (2019), which finds that exposure to more female peers in university teaching sections decreases women's likelihood of choosing male-dominated majors.

To understand which STEM subfields women are less attracted to when more female peers are present, we next estimate separate models in which we split STEM into four subgroups, shown in Panel A of Table 8: (1) Biology, (2) Math and Physics, (3) ICT and Engineering, and (4) Manufacturing and Construction. A comparison of the point estimates in Columns (1)–(4) reveals that the coefficients for women are relatively similar across STEM subfields. The point estimate

³⁰ As a robustness check, we also test whether results differ between students who attend a high school that is one of several in the municipality and those who attend the only high school in the municipality. If our estimates were driven by unobserved, time-variant selection into high schools, we would expect effects to differ substantially based on how much choice students have at the local level. Appendix Table A3 reports split sample regressions by the number of high schools in the municipality. For women, point estimates are very similar in regions that have only one high school in the municipality. For men, we find that the effect of peers seems to be somewhat larger in municipalities with only one high school. Although it is possible that peer effects may differ by the number of high schools in the municipality, we think that these results provide additional support for the validity of our peer effects estimates as we find the same effects for regions where students had a de facto very limited school choice.

for ICT & Engineering is marginally smaller and less precisely estimated, but not significantly different, from the other subfields. For men, the effect of having more female peers is stronger for entering Math and Physics and ICT and Engineering, which are the most male-dominated, gender-stereotypical STEM subfields.

We next ask which other study fields become more attractive to women and less attractive to men when having experienced a larger share of female high school peers. In Panel B of Table 8, we examine how the peer composition affects graduation from: (1) Health Sciences, (2) Education Studies, (3) Arts and Humanities, (4), Social Sciences, and (5) Business and Law. Only Health Sciences—a field heavily dominated by women—becomes significantly more popular among women who had more female peers in high school (Column 1).³¹ For men, we also find that more female peers make choices more gender-stereotypical: a larger share of female peers in high school decreases men’s probability of graduating with a college major within Health and Education Sciences. Columns (2)–(5) show that the high school gender composition does not influence women’s probability of completing a college degree in Education, Arts and Humanities, Social Sciences, or Business and Law. Consequently, our results suggest that women exposed to more female peers in high school substitute STEM studies with careers in the health sector. In Subsection C, we investigate the potential labor market consequences of these education choices in more detail.

[Table 8 here]

B. Underlying Mechanisms and Heterogeneity

Why does the gender composition in high school affect students’ decision to enter STEM fields?

³¹ Of all women who enter health sciences, 50 percent study nursing and midwifery, 20 percent study medicine, and 13 percent study therapy and rehabilitation.

We shed some light on the underlying mechanism by investigating whether high school gender composition affects final high school GPA, which students use to apply for college. We also split the sample based on parental educational level and field of education to learn more about whether some groups of students are more sensitive than others to the gender composition at their school. Considering heterogeneity in a parent's field of education might help us understand whether STEM role models at home moderate or perpetuate the influence of peers.

In order to assess the proposed mechanism, we investigate whether gender composition directly affects students' study ability or preparedness to enter STEM studies. This appears plausible as the peer effects literature has shown that gender composition can impact students' performance (Hill, 2017; Hoxby, 2000; Lavy and Schlosser, 2011). If the gender composition affects student performance differentially depending on the student's own gender, this effect may in part rationalize the effects on the choice of college major. Table 9 provides estimation results supporting such a mechanism. Column (1) in Table 9 shows that the gender composition does not affect women's GPAs; the point estimate is tiny and not statistically significant. On the contrary, male students achieve a higher GPA when they are exposed to a high school cohort with more female peers. Ten percentage points more female peers raises the GPA of male students by 1.3 percent of a standard deviation.³² Our finding is consistent with Lavy & Schlosser (2011) and Hill (2017), which show that men in high school and college achieve better grades when there are more female peers in their cohort. Importantly, the majority of STEM college programs in Denmark do not have a binding high school GPA threshold for admission. This rules out the possibility that gender composition mechanically affects STEM enrollment through the impact on male students' GPA.

³² All results in Table 9 are robust to the inclusion of cohort-by-school fixed effects.

The fact that male students achieve a higher GPA when a higher proportion of female peers are present may in part explain why fewer women and more men enter STEM studies in cohorts with more women. Given their higher GPAs, men might feel better prepared for STEM studies, which generally attract students with better high school grades. In contrast, women do not perform differently in high school, but might infer from the gender gap in high school GPA that they are less prepared or "suited" to enter STEM studies than their male peers. These results are consistent with Zölitz and Feld (2019), which also finds evidence of gender-specific performance responses that can rationalize students' specialization choices.

Table 9 further investigates whether the influence of female peers is similar for students with less-educated versus highly educated parents (Columns 3 and 4) and parents with STEM educations (Columns 5 and 6). Our motivation for splitting the sample by parental education is that students from nonacademic families may have less information about college majors and associated occupations and therefore be more sensitive to their peers' choices. If peers can provide information about study fields that is not available to students who have non-college educated parents, we would expect students from families with less-educated parents to be more sensitive to the peer composition. Similarly, students with a STEM-educated father or mother might have better information about STEM studies and careers. If parents serve as strong role models that shape the choices of their children, we would expect that students with a (same sex) parent in STEM are less sensitive to peer influences.

Column (3) shows estimates for the subsample of students who have parents without a college education, while Column (4) shows the same model for students who have one or two parents with a college degree.³³ The results show that the influence of peers is twice as strong for

³³ To facilitate comparison, Column (2) in Table 9 reports point estimates for the full sample from our preferred specification in Column (4) of Table 7.

women with parents without college education relative to women with college-educated parents. However, effects for men do not vary by parental education. One interpretation of these results is that women are more likely to follow the choices of their peers when they lack parents who have a greater capacity to help them find information about higher education or share their own college experiences. It is also possible that the study choice of parents who attended college provides an additional reference point that moderates the impact of peer effects in high school.

We next investigate whether effects are heterogeneous for students with a father or mother with a STEM education. Column (5) shows that the effect of peers on STEM completion is similar for women with a father in STEM and somewhat weaker and not statistically significant for men with fathers in STEM. These results suggest that men who have a STEM father are less susceptible to peer influences. Column (6) shows that these results are mirrored for women with STEM mothers. Strikingly, women with STEM mothers are not significantly affected by the peer gender composition. The point estimate is in fact positive, which suggests that STEM mothers seem to counteract the effect of peers on their daughters' specialization choice. While the group of individuals who have a mother in a STEM field is small, these results show that women who have a STEM mother as a role model are unaffected by peers. While these results remain suggestive, they could imply that access to a non-stereotypical same sex role model in the family is more powerful in shaping women's STEM interest than the influence of high school peers.

[Table 9 here]

C. Long-Run Effects on Labor Market Outcomes

Given our finding that high school gender composition affects the probability of enrolling in a STEM college major and completing such education, we now want to know whether these gender

peer effects also persist into occupational choice and whether they have consequences for labor earnings.

[Table 10 here]

Table 10 shows the impact of high school peers on labor market outcomes 15 and 20 years after high school entry (Columns 1 and 2). Fifteen years after high school entry, the median age of individuals is 29 years and most should have completed higher education and entered the labor market.³⁴ Table 10 shows that peers' influence on STEM field choice are persistent and closely mapped into women's occupational choices. A larger share of female high school peers reduces the probability that women work in a STEM-related occupation, while it has no impact on men's occupational choice. A 10 percentage-point increase in the proportion of female peers decreases the probability that women work in a STEM occupation 20 years after high school entry by 0.42 percentage points—a 3.9 percent decrease from the baseline (Column 2). Men's probability of working within STEM fields is similarly affected by the peer composition. This suggests that men who have more female peers become both more likely to enroll and graduate from STEM fields and are later more likely to end up working in STEM jobs.

Given these long-run effects on occupational choice, we next test whether individuals' labor earnings are affected. Does the proportion of female high school peers contribute to the gender wage gap? Columns (3) and (4) shed light on this question and show estimates for earnings 15 and 20 years after high school entry. We find that the high school gender composition has lasting effects on women's but not on men's earnings. A 10 percentage point increase in the proportion of female

³⁴ Brenøe and Lundberg (2017) show that after age 30, the share of a cohort that has completed a college or university degree is almost constant, indicating that by age 31 most individuals have completed higher education.

peers decreases women’s earnings 15 years after high school entry by 0.4 percentile points—nearly a one percent decline from the baseline—and has no impact on men’s earnings. Twenty years after high school entry, we still do not find any effect for men but an even larger effect of 0.66 for women. This increase in magnitude for women is in line with a similar increase in the effect on their STEM occupational participation. The estimate from our second strategy (Panel B), which includes cohort-by-school fixed effects, suggests that having a 10-percentage-point-larger share of female high school peers increases the gender earnings gap by 0.75 percentile points, corresponding to an increase of 5.4 percent (Column 4). Thus, our results show that high school gender composition has lasting impacts on the gender wage gap and one potential channel of this effect might be through the impact on STEM participation.

D. Long-Run Effects on Fertility

After having established that high school gender composition affects women’s participation in STEM and earnings, we next examine the impact of female peers on fertility. Although fertility is an interesting outcome in itself and female peers may directly shape fertility preferences, it is also possible that starting a STEM career influences the timing and number of children. A more competitive environment, longer working hours, and lower job flexibility might make it harder to combine children and work obligations for women in STEM careers. Because of differences in work environments in terms of family-friendliness, women in STEM fields may decide to have fewer or no children. In this case, changes in fertility could be interpreted as an unintended consequence of the high school gender composition that "pushed" some individuals in or out of STEM careers. Alternatively, if the high school gender composition directly affects fertility preferences, then part of the documented effects on the gender wage gap could be because having children reduces earnings for women (Kleven et al. 2018; Lundborg et al. 2017). In such case,

lower earnings for women should not be attributed to their lower probability of staying out of STEM fields when having more female peers, but may instead be a consequence of the "career cost of children" (Adda et. al., 2017).

[Table 11 here]

Table 11 documents the medium- and long-run consequences of high school gender composition on fertility. Columns (1)–(4) provide a detailed analysis on the timing of fertility effects on the extensive margin. While Column (1) shows little effect on fertility during the first five years after high school entry, we see a clear impact on the probability of having any children within 10 years after high school entry when individuals are around 26 years old and, for the most part, have entered the labor market (Column 2). We find that having a larger proportion of female high school peers increases women’s and decreases men’s probability of having any children by the age of 26. Column (4) shows that 20 years after high school entry, women are no longer less likely to have any children, but we still find a persistent effect for men.³⁵

In Columns (5)–(8) of Table 11, we estimate effects at the intensive fertility margin by testing whether female peers affect the number of children individuals have. We find that women who had more female peers and thus were less likely to enter STEM careers, have more children by the age of 36. The increased fertility effect becomes visible shortly after the time of college completion and doubles within the first couple of years in the labor market (Column 7). By the time individuals are 36 years old, women exposed to 10 percentage points more female peers have on average 0.02 more children, an increase of about 1.0 percent from the baseline of 1.66 children

³⁵ Restricting the sample to older cohorts reveals very similar effects on fertility through older ages. Therefore, the reported effects are close to effects on complete fertility, especially for women.

(Column 8). For men, we find that those exposed to more female peers have significantly fewer children by age 36.

Our results show that the proportion of female peers has not only significant impacts on study choice, occupational choice, and earnings, but affects fertility as well. Strikingly, women have their first child earlier and increase the number of children they have when they have a larger share of female high school peers. If high school peers already affect men's and women's fertility preferences before choosing their field of study, women's shift from STEM to health-related studies (and the reverse for men) might partly be explained by changes in the desired number of children.

These findings on fertility raise the question of whether the negative effect of having more female high school peers on women's earnings documented in Table 10 is driven by women's non-participation in STEM or by their increased fertility. Although we ultimately cannot distinguish between these mechanisms, our results are consistent with Kleven et al. (2018). Using Danish administrative data (similar to our data), they document that men and women experience very similar trends in labor earnings before the arrival of their first child. They show, however, that while women experience a large decline in earnings at the time of their first childbirth and still have earnings 20 percent below their initial level ten years later, men do not experience any change in their earnings after having children. Given the results of Kleven et al. (2018), our result that women who were exposed to more female peers have lower earnings could in part be due to changed fertility patterns.

Our finding that the peer gender composition causally affects the timing and number of children has previously not been documented in the existing literature. More broadly, our paper relates to a number of other studies documenting how the social environment shapes fertility decisions. Balbo and Barban (2014) use information on friendship networks in Add Health data and show that friends' childbearing is positively related to individuals' own probability of

becoming a parent. Kuziemko (2006) shows that the probability of having a child rises substantially in the two years after a niece or nephew is born to an individual's sister, but finds no impact of children born to brothers. In light of these two papers, our finding that having more female peers increases women's probability of having children earlier might, in part, be because having more female peers (and likely more female friends) also implies having a network of people who have children sooner than when women have proportionally more male peers. Moreover, Ciliberto et al. (2016) study fertility peer effects in the workplace in Denmark and show that fertility among workplace peers of similar age and education groups is positively correlated. Relatedly, Brenøe (2018) finds that the sibling sex composition does not affect the timing or number of children.

VI. Conclusion

Using Danish administrative data, this paper shows that the gender composition of high school peers affects students' decisions to undertake STEM studies in higher education. Our results show that a higher proportion of female high school peers makes study choices more gender-stereotypical. With more female peers present, women become less likely to enter STEM fields and more likely to enter Health Studies. Men also behave more gender-stereotypically and become more prone to enter STEM studies when exposed to more female peers. For women, these gender peer effects in study choice have remarkably persistent long-run effects on occupational choice, which remain visible 20 years after high school entry. Women who by chance were exposed to more female peers are less likely to work in STEM occupations and have lower earnings 20 years after high school entry. Strikingly, the high school gender composition also affects individuals' fertility.

Although our results are based on one country, our findings are consistent with the evidence provided by Hill (2017) as well as Zölitz and Feld (2019), who suggest that gender peer effects

shape preferences for study fields and thereby lead students to systematically different career trajectories. Our evidence on the underlying mechanisms remains suggestive, but indicates that a higher proportion of female peers affects the gender gap in high school GPA and may therefore foster the gender gap in STEM preparedness, which gives students reason to believe that they have a comparative advantage in a more gender-stereotypical college major. We also find that women with STEM-educated mothers are unaffected by the gender composition, which suggests that salient female role models may be able to counteract peer pressures in high school. Our findings emphasize that the social environment directly affects students' decisions to specialize within STEM fields and educational and occupational choices more generally. Moreover, our results suggest that manipulating the gender composition in a given environment through affirmative action policies to achieve gender balance may have adverse and unintended consequences for fertility, gender segregation in college majors, and the labor market.

Table 1: Descriptive Statistics – continued

Panel B: Student-level background variables						
Mother has tertiary education	81820	0.3557	0.4787	100391	0.3911	0.488
Mother has upper secondary education	81820	0.3696	0.4827	100391	0.3648	0.4814
Mother has less than upper secondary education	81820	0.2558	0.4363	100391	0.2208	0.4148
Mother in STEM field	81820	0.056	0.230	100391	0.054	0.225
Father has tertiary education	81820	0.3759	0.4844	100391	0.4305	0.4951
Father has upper secondary education	81820	0.3716	0.4832	100391	0.3526	0.4778
Father has less than upper secondary education	81820	0.2053	0.404	100391	0.1602	0.3668
Father in STEM field	81820	0.343	0.475	100391	0.323	0.468
First-generation immigrant	81820	0.008	0.091	100391	0.012	0.107
Second-generation immigrant	81820	0.006	0.075	100391	0.008	0.088
Child is adopted	81820	0.009	0.095	100391	0.007	0.084
Mother's age at child's birth	81052	26.429	4.769	99156	26.563	4.752
Mother <22 years at child's birth	81052	0.141	0.348	99156	0.133	0.340
Firstborn	81820	0.505	0.500	100391	0.516	0.500
Number of siblings	81689	1.472	0.908	100077	1.436	0.901
Lives with both parents at age 10	81820	0.861	0.346	100391	0.841	0.366

Panel C: School-level variables						
Proportion female peers	81820	0.454	0.066	100391	0.447	0.067
Number of students in cohort	81820	107.878	30.776	100391	108.470	31.053
Cohort	81820	1987	4.338	100391	1987	4.345
Number of feeding municipalities	81820	6.330	3.304	100391	6.305	3.215
2+ high schools in municipality	81820	0.446	0.497	100391	0.459	0.498

NOTE: Annual labor earnings are measured in thousand Danish kroner (1 USD = 6.6 DKK). Annual labor earnings are adjusted for 2015 prices.

Table 2: Balancing Test I: Does Student Gender Predict Proportion of Female Peers?

	Dependent variable: Proportion female peers in high school cohort							
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Female	0.0009 (0.0013)	0.0014 (0.0010)	0.0009 (0.0009)	0.0012 (0.0009)	0.0008 (0.0013)	0.0012 (0.0010)	0.0007 (0.0009)	0.0011 (0.0009)
Observations	182211	182211	182211	182211	182211	182211	182211	182211
p-value of "Female" coefficient	0.491	0.186	0.344	0.174	0.521	0.237	0.443	0.230
High school and cohort fixed effects	✓	✓	✓	✓	✓	✓	✓	✓
Individual-level and high school-level controls	-	-	-	-	✓	✓	✓	✓
F-test for joined significance of individual level variables					0.465	0.582	0.270	0.324
School-specific time trends	-	linear	quadratic	cubed	-	linear	quadratic	cubed

NOTE: The dependent variable in all columns is the proportion of female peers in the high school cohort of an individual. All columns include cohort fixed effects and school fixed effects. Following the Guryan, Kroft, and Notowidigdo (2009) correction method, we control for the leave-out mean of the proportion of female peers across cohorts within the school in all columns. *School level controls* included in Columns (5)–(8) include an indicator if any student in the cohort is older than 20 years at high school entry, dummies for number of students without information on gender (ranging from 0 to 2), indicators for large changes in cohort size compared to previous years, the female share in the language track, an indicator if the high school has no language track, indicators for exposure to experiment on course curriculum, and cubed cohort size.

Table 3: Balancing Test II**Does Proportion of Female Peers Predict Student Background Characteristics?**

	(1)	(2)	(3)	(4)	(5)	(6) Across all models
Number of performed tests	38	38	38	38	38	190
Number significant at 1 percent level	1	1	0	0	0	2
Number significant at 5 percent level	1	1	0	1	1	4
Number significant at 10 percent level	4	5	2	4	2	17
Share significant at 1 percent	0.026	0.026	0.000	0.000	0.000	0.011
Share significant at 5 percent	0.026	0.026	0.000	0.026	0.026	0.021
Share significant at 10 percent	0.105	0.132	0.053	0.105	0.053	0.089
School level controls	-	✓	✓	✓	✓	
School-specific time trends	-	-	linear	quadratic	cubed	

NOTE: This Table is based on 190 separate OLS regressions shown in Appendix Table A1. All regressions include cohort fixed effects and school fixed effects. *School level controls* included in Columns (2)–(5) include an indicator if any student in the cohort is older than 20 years at high school entry, dummies for number of students without information on gender (ranging from 0 to 2), indicators for large changes in cohort size compared to previous years, the female share in the language track, an indicator if the high school has no language track, indicators for exposure to experiment on course curriculum, and cubed cohort size. Standard errors are clustered at the school-cohort level.

Table 4: Balancing Test III
School Level Autocorrelation in the Proportion of Female Students

For what proportion of schools does the proportion of female students in t-1 significantly predict the proportion female students in t?

Proportion of school coefficients	(1)	(2)	(3)	(4)	Across all models
Significant at 1 percent level	1.57%	0.79%	0.79%	0.79%	0.98%
Significant at 5 percent level	2.36%	2.36%	3.15%	5.51%	3.35%
Significant at 10 percent level	6.30%	5.51%	8.66%	14.96%	8.86%
School-specific time trends	-	linear	quadratic	cubed	

NOTE: This table provides summary statistics of significance for 127 separate bivariate school-level regressions that only include the respective school-specific trend variable(s).

Table 5: Correlation between Proportion of Female Peers in Math and Language Track

	Proportion female peers in language track		
	(1)	(2)	(3)
Proportion female peers in language track	-0.015 (0.027)	-0.017 (0.026)	-0.035 (0.026)
N	1866	1866	1866
Mean	0.449	0.449	0.449
Individual & peer level controls	-	✓	✓
School-specific time trends (linear)	-	-	✓

NOTE: The level of observation is cohort-by-school. All regressions include school and cohort fixed effects. In total, 11 school-cohorts in the sample do not have the language track (corresponding to 727 students). Standard errors clustered at the school level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 6: Impact of High School Gender Composition School Track and Cohort on STEM Enrollment and STEM Completion

Panel A: Dependent variable: STEM enrollment				
	(1)	(2)	(3)	(4)
Female * Proportion female peers in math track	-0.141*** (0.026)		-0.132*** (0.026)

Female* Proportion female peers in school cohort				-0.073*** (0.028)
Male* Proportion female peers in school cohort				0.099*** (0.030)
Female	-0.030** (0.013)	-0.021 (0.026)	0.043 (0.028)	-0.019 (0.021)
Observations	181484	181484	181484	181484
Mean dependent variable women	0.135	0.135	0.135	0.135
Mean dependent variable men	0.253	0.253	0.253	0.253
p-values of test for gender equality of "Proportion female peers"	<.0001	<.0001	<.0001	<.0001

NOTE: The dependent variable in all columns of Panel A is an indicator for whether the student enrolled in a STEM program in college within 20 years after high school entry. The dependent variable in all columns of Panel B is an indicator for whether the student's highest completed education is at least at the college level and is within STEM. All models control for cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years, as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1. All results are robust to the inclusion of cohort-by-school fixed effects. The sample excludes those students attending a school-cohort without a language track (11 school-cohorts, corresponding to 727 students), which explains the difference in sample sizes between this table and Table 7. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 7: The Impact of Peer Gender on STEM Enrollment and STEM Degree Completion

Panel A: Dependent Variable: STEM Enrollment

School-specific time trends	-	-	-	linear	quadratic	cubed	-
Cohort-by-School fixed effects	-	-	-	-	-	-	✓

NOTE: The dependent variable in all columns of Panel A is an indicator for whether the student enrolled in a STEM program in college within 20 years after high school entry. The dependent variable in all columns of Panel B is an indicator for whether the student's highest completed education is at least at the college level and is within STEM. Column (7) does not include peer-level variables because these are highly collinear with the cohort-by-high school fixed effects. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 8: Impact of High School Gender Composition on Graduation in Various Fields

Panel A: STEM Subfields	Biology	Math / Physics	ICT / Engineering	Manufacturing / Construction

<i>p</i> -values of test for gender equality of "Proportion female peers"	0.110	<.0001	<.0001	<.0001	0.002	0.241

NOTE: The dependent variable in column (1) is the grade point average (GPA) at the end of high school, standardized with a mean of zero and standard deviation of one, and is observed for those students who completed general academic high school. All models control for cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years, as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1. In the sample, 6 percent of mothers and 32 percent of fathers hold STEM degrees. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Mean dependent variable men	0.246	0.255	62.567	70.615

NOTE: The dependent variable in columns (1) and (2) is an indicator for working in a STEM occupation; it takes the value of one if the individual for at least half the period works in a STEM occupation within the Danish version of ISCO codes 21, 25, 31, or 35 (Science and Engineering Professionals, Information and Communications Technology Professionals, Science and Engineering Associate Professionals, or Information and Communications Technicians). The dependent variable in columns (3) and (4) is the average of the individual's labor earnings percentile during the five-year period, calculated by year of birth and age using the entire Danish population as a reference group. All models in Panel A control for school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years, as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1. All models in Panel B control for cohort-by-school fixed effects and individual controls. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Mean dependent variable women	0.019	0.208	0.611	0.796	0.02	0.259	1.015	1.656
Mean dependent variable men	0.007	0.108	0.444	0.683	0.007	0.127	0.67	1.317

NOTE: Five years after high school entry, individuals should be at the beginning of their college studies. Ten years after high school entry, individuals are around 26 years old and should have completed college education. Fifteen years after high school, individuals have been in the labor market for approximately five years if they attended college. Twenty years after high school, individuals are about 36 years old. All models in Panel A control for cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1. All models in Panel B include cohort-by-school fixed effects and individual controls. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

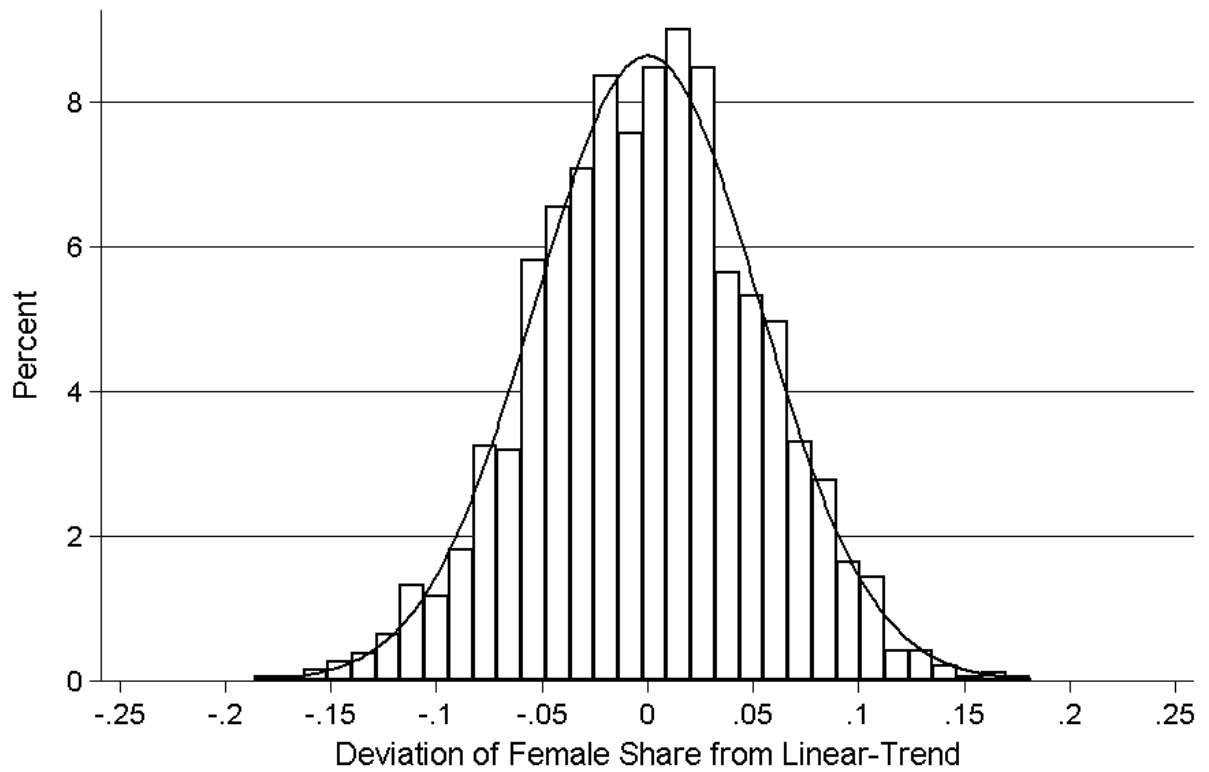

FIGURES

Figure 1: Correlation between Proportion of Female Peers and STEM Degree Completion

NOTE: The graph shows a bin scatter plot by gender using 30 bins. STEM Degree is measured as highest completed degree at the college level or higher 20 years after high school entry.

Figure 2: Year-to-Year Variation in the Proportion of Female High School Peers Within High Schools

NOTE: This figure illustrates the year-to-year variable in the proportion of female high school peers within high schools, plotted along with the normal distribution. More precisely, it plots the predicted proportion of female peers at the school-cohort level from a regression regressing the proportion of female peers on cohort and school fixed effects and school-specific linear time trends. Each high school-cohort represents one observation.

School level controls	-	✓	✓	✓	✓
School-specific time trends	-	-	linear	quadratic	cubed

NOTE: Each cell in this table is estimated with a separate regression including school and cohort fixed effects. The dependent variable in each cell is the proportion of female high school peers. *School level controls* included in Columns (2)–(5) are an indicator if any student in the cohort is older than 20 years at high school entry, dummies for number of students without information on gender (ranging from 0 to 2), indicators for large changes in cohort size compared to previous years, the female share in the language track, an indicator if the high school has no language track, indicators for exposure to experiment on course curriculum, and cubed cohort size. Standard errors in parentheses are clustered at the school-cohort level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table A2: The Impact of Peer Gender on High School Graduation, College Enrollment, and Higher Education Degree Completion

	(1)	(2)	(3)
	Completed academic high school	Ever enrolled in higher education	Completed higher education degree
Female * Proportion female peers	0.017 (0.017)	-0.010 (0.024)	0.000 (0.027)
Male * Proportion female peers	0.017 (0.017)	-0.030 (0.022)	-0.035 (0.026)
Female	0.024** (0.010)	0.005 (0.014)	0.045*** (0.016)
N	182211	182211	182211
Mean	0.909	0.789	0.677
<i>p</i> -values of test for gender equality of "Proportion female peers"	0.992	0.523	0.315

NOTE: The dependent variable in Column (1) is equal to one if the student completed academic high school within five years after high school entry. The dependent variable in Column (2) is equal to one if the student ever enrolled in college studies and the dependent variable in Column (3) is equal to one if the student ever completed any college education. All models control for school-specific time trends, cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table A3: Robustness Check—Main Results by Number of Schools in the Municipality

Subgroup	Full sample	Municipality with only 1 high school	Municipality with 2+ high schools
Dependent variable:	STEM completion	STEM completion	STEM completion
	(1)	(2)	(3)
Female * Proportion female peers	-0.097*** (0.022)	-0.088*** (0.030)	-0.097*** (0.032)
Male * Proportion female peers	0.092*** (0.023)	0.107*** (0.032)	0.064** (0.033)
Female	-0.033** (0.013)	-0.036* (0.019)	-0.037** (0.019)
Observations	182211	99599	82612
Mean	0.200	0.200	0.199
<i>p</i> -values of test for gender equality of "Proportion female peers"	<.0001	0.001	0.046

NOTE: All models control for school-specific time trends, cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1. Standard errors clustered at the school-cohort level are in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Figure A1: High School Gender Composition and STEM Enrollment Non-Linear Effects

NOTE: This figure shows point estimates obtained from OLS regression. Instead of including the continuous measure of the proportion of female high school peers interacted with the gender dummy, this regression includes five dummies for the high school gender composition interacted with gender. The dependent variable is STEM study enrollment. Vertical lines refer to the 95 percent confidence intervals. The model controls for school-specific linear time trends, cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years, as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1.

Figure A2: High School Gender Composition and STEM Graduation – Non-Linear Effects

NOTE: This figure shows point estimates obtained from OLS regression. Instead of including the continuous measure of the proportion of female high school peers interacted with the gender dummy, this regression includes five dummies for the high school gender composition interacted with gender. The dependent variable is STEM graduation. Vertical lines refer to the 95 percent confidence intervals. The model controls for school-specific linear time trends, cohort fixed effects, school fixed effects, cubed cohort size, indicators for large cohort size changes compared to previous years, as well as a large set of individual and leave-out-mean peer controls shown in Panel B of Table 1.
