Reshaping global trade: the immediate and long-term effects of bank failures

Abstract

I show that a disruption to the financial sector can reshape the patterns of global trade for decades. I study the first modern global banking crisis originating in London in 1866 and collect archival loan records that link multinational banks headquartered there to their lending abroad. Countries exposed to bank failures in London immediately exported significantly less and did not recover their lost growth relative to unexposed places. Their market shares within each destination also remained significantly lower for four decades. Decomposing the persistent market-share losses shows that they primarily stem from lack of extensive margin growth, as the financing shock caused importers to source more from new trade partnerships. Exporters producing more substitutable goods, those with little access to alternative forms of credit, and those trading with more distant partners experienced more persistent losses, consistent with the existence of sunk costs and the importance of finance for intermediating trade.

I. INTRODUCTION

How much and for how long do financial crises impact the patterns of international trade? Trade relationships are highly stable and generally understood to be shaped by slow-moving forces of comparative advantage such as differences in technologies, endowments, and institutions. In most trade frameworks, transient shocks like financial crises can only have temporary effects. Yet models with multiple equilibria stress that large shocks can dislodge the economy from a given equilibrium and leave it permanently in a different one.¹ Whether financial shocks can induce such an equilibrium shift remains unknown.

Establishing the long-run effect of financial shocks on the patterns of global trade is difficult for multiple reasons. First, economic fundamentals simultaneously impact exports and banking sector health. Second, even when it is possible to isolate an exogenous shock to the financial sector, data are usually limited to short-run outcomes within one country or require combining episodes from institutionally dissimilar countries and time periods. Ideally, one would be able to trace the long arm of history over uninterrupted decades in a setting where all countries are exposed to the same shock to their financial institutions.

I address these challenges by studying the 1866 banking crisis that originated in London but which disrupted short-term bank-intermediated financing in almost every country in the world. At the time, Britain was the center of the global financial system: British banks were the dominant providers of short-term credit and operated in countries that accounted for 98% of world exports.² The crisis propagated from London around the world in varying degrees based on the network of British banks. This variation in the intensity of the shock allows me to implement an event study difference-in-differences estimation that compares exports volumes across locations that were more or less exposed to British bank failures, before and after 1866.

The banking crisis in this paper has many attractive features for estimating the immediate to long-run effects of a financing shock on the patterns of trade around the world. First, it was caused by the unexpected failure of a fraudulent financial intermediary, the firm Overend & Gurney. This event triggered severe bank runs on London's deposit-issuing banks, and ultimately 16% of multinational banks headquartered in London failed and ceased both domestic and foreign operations. Second, in contrast to much of the existing literature on long-run outcomes that relies primarily on cross-sectional evidence, this setting allows

¹There is a literature on historical persistence in which multiple equilibria, institutional and cultural characteristics, and agglomeration forces can entrench the effects of a one-time shock in the economy (see Nunn (2014) for an overview).

²Calculated using the locations and operations of British and non-British banks and values of exports across countries in 1865.

me to trace out the full dynamics over time. This allows me to study the evolution of trade patterns both before the crisis to show the lack of differential pre-trends, and afterwards to examine the speed and dynamics of recovery (or lack thereof). Third, locations' exposure to bank failures is continuously measured and based on observed bank activity, which has the advantage of being more precise than indicator variables of financial crises in most macro-oriented studies. Finally, the dominance of British banks makes it possible to compare the impact around the world using additional cross-country heterogeneity to better understand the mechanisms.

Pure randomness in bank failures delivers the exogenous variation sufficient for identification, and I provide narrative and quantitative evidence that the crisis followed a panic scenario where bank failures are mostly unrelated to observable measures of bank solvency. I show that the main observable characteristics correlated with a bank's failure is a public connection to the firm Overend & Gurney. Crucially, Overend & Gurney was not itself involved in trade-related activities, so this connection is unlikely to be correlated with exports fundamentals in the banks' operating regions. Moreover, Overend & Gurney's failure was due to fraudulent mismanagement that was so well-concealed that the firm had successfully "IPO'd" just nine months prior. Consistent with the environment of limited knowledge during the panic, there is also no relationship between the Overend connection and quantitative measures of bank health, liquidity, and risk-taking, or with narrative accounts of the banks' investment opportunities and growth in their operating regions. This panic scenario distinguishes the setting here from other historical banking crises that were triggered by negative real economic shocks.

More formally, identification does not require pure bank failure randomness nor does it require that the geographic distribution of bank subsidiary operations is random. It only requires randomness with respect to the characteristics of the locations these banks were operating in, to the extent that those characteristics impacted exports. In a difference-in-differences setting, the identifying assumption is that there are no simultaneous shocks to a location that cause both its exports to decline and the banks operating there to fail (Borusyak et al., 2022). I provide a number of covariate balance tests of bank exposure to location characteristics, control for a large number of observables, and show graphical evidence for the lack of pre-trends to support this identifying assumption.

My analysis necessitated constructing several new datasets of historical trade and financing activity around the world, both within and across countries. First, I measure cities' and countries' exposures to British bank failures from over 11,000 handwritten archival loan records that represent the distribution of pre-crisis British bank lending relationships around the world. To my knowledge, these are the only data with global coverage of the dominant

financial center’s banking relationships in any time period. Second, for each bank, I collect balance sheets, shareholder meeting transcripts, and other narrative sources before and after the crisis. Third, for each country, I assemble and standardize a panel of bilateral exports values spanning the period 1850–1914. I complement these country-level measures with the 1865 pre-crisis industry composition of exports from contemporary trade statistics reports. Fourth, within countries, I measure exporting activity with daily port-level ship movements from the *Lloyd’s List* newspaper for the two year window around the crisis.

I compare the exports of more versus less-exposed locations before and after the crisis in the immediate and long-run horizons and at various levels of geographic aggregation. My first set of results shows that the financing shock immediately lowers exports volumes. Countries exposed to a one standard deviation increase in bank failures have 8.5% lower exports one year later. I find very similar point estimates when using within-country, across-port variation that allow me to include country-by-period fixed effects. Doing so nets out time-varying unobserved heterogeneity at the country level, including other changes in a country’s trade costs, that could potentially drive the results. These results are robust to alternative specifications, count regression methods, and subsample restrictions.

In my second set of short-run results, I find that on the extensive margin, exporters more exposed to the shock have fewer trade partners afterwards and are less likely to engage in international trade at all. These differences are due to a lower propensity to start trading as opposed to an increase in the likelihood of stopping.

My third set of results shows that the export losses are highly persistent in the long-run, both in the aggregate of total exports and in terms of exporter market shares within destinations. Using the full panel of bilateral trade data allows me to control for demand shocks with importer-by-time fixed effects and to include the host of measures of resistance to trade between countries that are standard in empirical gravity frameworks. This specification has a straightforward reduced form interpretation as the relative market-share difference between more versus less exposed exporters within the average destination each year. In the baseline estimation, I find that importers bought on average 18% less each year from exporters with a one standard deviation higher exposure to bank failures after the crisis, with effects significantly different from zero for four decades. There is little recovery, and the estimated hysteresis is robust to controlling for a wide variety of contemporary shocks and initial macro-economic conditions. Simulated placebo shocks also fail to recreate these patterns.

The reduced form estimation in the baseline provides an elasticity that captures the overall effect of the financing shock on trade flows after controlling for other observable factors that are known to impact trade. While the institutional context indicates that trade

financing is likely an important channel for these effects, and in a series of exercises I directly control for other potential channels, it is impossible to fully rule out other mechanisms.

By making the stronger assumption that the financing shock acts as a pure change to trade costs, it is possible to estimate a trade cost elasticity based on structural gravity. This approach arises from many classes of micro-founded trade models and shows that any changes in direct trade costs between two countries also affect prices in general equilibrium, which in turn indirectly affect trade flows for all countries through multilateral resistance terms (e.g., Anderson and Van Wincoop, 2003; Head and Mayer, 2014). The estimated coefficients have the advantage of being theoretically grounded, directly comparable to other trade cost shocks in the literature, and a necessary input for calculating welfare effects.

I follow the procedure in Baier and Bergstrand (2009) implemented by Berger et al. (2013) that uses a first-order log-linear approximation of changes in multilateral resistance to estimate the market share effects under this assumption. I find an average post-crisis elasticity of -1.88 (standard error 0.84) that is 37% larger in magnitude than the reduced form (although the 95% confidence intervals include the reduced form estimates). Taken at face value, the larger magnitude from this approach relative to the reduced form elasticity indicates that the general equilibrium effects produced by the trade cost shock amplify the direct effect of financial shocks on trade. However, given that the structurally motivated elasticity requires the strong interpretation that bank failures only affected trade costs, I present the reduced form results as the baseline.

The empirical finding of persistence motivates a conceptual framework featuring sunk costs of establishing relationships and substitutability across exporters. The main assumptions of the framework follow from the details of the institutional context that features highly substitutable goods (commodities trade), high sunk costs (slow communication), and intense competition (rapidly expanding trade networks in the 1860s and 70s). The framework predicts long-run market share losses for exporters even holding demand constant. These effects come from importers expanding their trade relationships on the extensive margin once the financing shock raises their existing exporters' prices. Empirically, I show that importers whose trade partners were more exposed to the shock formed more new relationships, resulting in a lower share of their total imports coming from pre-existing relationships. This extensive margin growth by importers map onto the market share losses by exposed exporters in the baseline specification.

When looking at whether exposure to bank failures affected countries' *imports*, I find no effect. This corroborates the evidence that these international banks were primarily financing exporting activity, i.e. the supply side of trade, but had no role in financing consumption. Therefore, unlike in 2008-9, the relative reduction in trade did not appear to be

demand-driven but was rather a supply shock.

In the final section of the paper, I provide evidence that trade patterns changed in a manner consistent with the financing shock impacting countries' costs of exporting, likely through a trade financing channel. First, exporters that were likely to provide similar goods benefitted when their competitors were exposed to the shock. This effect is true both across countries (where countries in the same geographical region produce and export similar bundles of goods) and within countries (where ports in the same country ship similar bundles of goods). In both cases, after controlling for a country or port's own exposure to bank failures, the average exposure of their neighboring competitors positively benefit their own exports.

Second, exporters whose exposure to bank failures are likely to be dampened by access to alternative sources of financing during the shock had lower losses. Third, relationships that likely relied less on trade finance, such as those that were physically closer, experience less persistent losses than more distant relationships.

I conclude by benchmarking the estimated effects against those available in the literature, which primarily focus on short-term effects, and I show that these losses at short horizons are very similar to those due to other barriers to trade and for other types of crises.

This paper contributes to the literature providing empirical evidence of the hysteretic effects of a temporary shock. Multiple equilibria are theoretically possible in many contexts, and the work by Davis and Weinstein (2002, 2008), Redding et al. (2011), and Bleakley and Lin (2012) provide early empirical evidence from various settings showing both recovery and persistence in urban agglomeration.³ With respect to international trade, Baldwin (1988, 1990); Baldwin and Krugman (1989) provide theoretical results of persistence arising from sunk costs. Empirically, firms' and countries' history of exporting predicts contemporary trade patterns (Eichengreen and Irwin, 1998; Bernard and Jensen, 2004), and sunk costs appear to be large (Roberts and Tybout, 1997), but none of these provides direct evidence from an exogenous shock, nor guidance on how long these effects can last. This paper also highlights a separate mechanism showing how the advantage of uninterrupted financial access while integrating into world markets during a period of globalization impacts cross-country trade patterns and could be viewed as a critical juncture for generating first-mover advantages (Krugman, 1991; Allen and Donaldson, 2020).

It also relates to the macroeconomic literature that has found that financial crises have particularly large effects on many components of the economy, such as output, consumption,

³Related papers showing persistent effects of temporary historical events include Nunn (2008) on the African slave trade, Dell (2010) on forced labor institutions in Peru, Sequeira et al. (2020) on the age of mass migration in the US for development, Juhász (2018) on the Napoleonic blockade for industrial growth, and Hanlon (2015) on the US Civil War for innovation.

and employment (Reinhart and Rogoff, 2009; Barro and Ursúa, 2008; Chodorow-Reich, 2014). Cerra and Saxena (2008, 2017) show that GDP dynamics following financial shocks (and crises more generally) do not recover at all, which relates to a classic empirical business cycle literature that recessions are not simply temporary cyclical events but rather have a highly persistent component (Blanchard and Summers, 1986; Campbell and Mankiw, 1987).

In the modern economy, credit conditions in peripheral countries have been found to be disproportionately associated with capital flows from the current global financial center (Eichengreen and Rose, 2004; Maggiori, 2017). Both global banks and an international reserve currency can transmit financial conditions in the core to the periphery, thereby amplifying international credit cycles (Goldberg and Tille, 2009; Amiti et al., 2019). The setting of a major shock to the pre-WWI global hegemon in this paper illustrates how conditions in the dominant financial market affect real activity globally, particularly in sectors dependent on external capital flows.

Finally, this paper speaks to the debate on the role of finance in trade. Many studies use cross-industry variation in external finance dependence and measure a country or firm's access to finance as a static source of comparative advantage, finding that financial constraints differentially affect exports for countries or firms specializing in financially-dependent sectors (e.g., Manova, 2013; Muûls, 2015; Iacovone et al., 2019; Beaumont and Lenoir, 2019). The trade response to financial shocks also gained prominence following the Great Trade Collapse of 2008, and while some studies find financial conditions to be a first-order determinant of trade flows (Chor and Manova, 2012) others attribute the majority of the decline to demand and inventory (Alessandria et al., 2010; Bricongne et al., 2012; Eaton et al., 2016). I provide causal evidence using bank-level variation as in Amiti and Weinstein (2011); Paravisini et al. (2014) and extend the analysis to every country over much longer periods.

The paper is organized as follows: the next section discusses the historical context, Section III discusses the historical data sources, and Section IV describes the identification strategy. Section V summarizes the conceptual framework and reports the main results, and Section VI provides evidence on the source of persistence and heterogeneous effects. Section VII concludes.

II. HISTORICAL CONTEXT

II.A Trade finance & British banking dominance

Contractual and information frictions were a major barrier to establishing international trading relationships in the 19th century (Reber, 1979), just as they are today. The long lag between the initial shipment by exporters, the receipt of goods by importers, and their final sale to consumers means that purchase and payment is staggered, and there is room for default on both sides. Contractual terms over quantities or quality may be difficult to enforce when the exporter is risky, which is particularly likely for exporters in countries of low institutional quality or in new, riskier markets (e.g., Antràs and Foley, 2015; Schmidt-Eisenlohr, 2013). In that case, importers are unwilling to directly finance exporters through cash in advance payments, raising exporters' working capital costs.⁴ Information frictions were also high historically, which further impeded trade (Steinwender, 2018).

Banks were well-positioned to overcome these frictions because they operated locally, which gave them superior knowledge of an exporting firm's risk and allowed them to take collateral, often in the form of goods shipped.⁵ Their role in learning about exporters while providing them with short-term financing means that they stimulated international trade both by easing contractual frictions and by facilitating costly information flows.⁶ Their business model also benefited from a form of exorbitant privilege due to the pound sterling's centrality: banks paid low rates on domestic liabilities (deposits) in the largest capital pool in the world and received high rates on their foreign assets (trade finance) abroad.⁷ These structural advantages stemming from the London connection contributed to British banking dominance and global reach such that by 1865 these banks operated in almost every country and well beyond the British empire.

⁴Contemporary 19th century accounts indicate that uncertainty over payments made it difficult for exporters to operate (Reber, 1979, p.75).

⁵For example, the Bank of London and the River Plate "attempted to assess the credit standing of its customers, although a good deal of business was carried on through personal contacts and oral agreements. The board of directors of the bank sought to establish credit guidelines. It stipulated that no credit exceeding £20,000 should be given to any single person or firm. The bank evaluated the respectability and soundness of mercantile houses and curtailed credit when necessary [...] Each credit case was worked out individually with the house, and the amount of credit extended depended on the bank's knowledge of the customer's reliability," (Reber, 1979, p. 60-61).

⁶They were not permitted to act as general commercial banks and invest in long-term, illiquid assets in their local markets abroad (Chapman, 1984). For example, it was in the Chartered Bank of India Australia and China's prospectus that it would be "[prohibited from] the making of advances on landed or other immovable Securities, or on growing crops."

⁷The English and Swedish Bank described this business model in the following way in their shareholder meeting on January 15, 1867: "When the bank was formed it was intended to receive money in England on deposit at the ordinary rate, and lend it out in Sweden at the high rate which was paid there upon such transactions [...] Money was cheap in England, but a very high rate could be obtained for it in Sweden."

The primary instrument used to finance international trade were short-term, often collateralized, loans called “banker’s acceptances” or “bills of exchange.”⁸ Acceptances were “IOUs” written between a borrower (an exporting firm) and a creditor (in this case the British bank) in which the creditor “accepted” that the borrower would repay him in the future (usually after 3–6 months). This source of financing provided exporters with working capital costs during the duration of shipment. Contemporaries emphasized that British banks were not limited to funding trade with Britain, and that in fact the “bill on London” was predominant even for trade that had no British counterparties.⁹

These features of the institutional context where banks primarily held short-term bills as assets and were usually explicitly prevented from making illiquid investments is the reason I interpret their presence as reflecting the supply of trade financing.¹⁰

A banker’s acceptance also had the unique legal feature of being guaranteed by the acceptor, meaning that in the case of default by the original borrower, the bank was responsible for the debt. This bank guarantee transformed these instruments from bearing the idiosyncratic risk of the individual exporter into bearing the better known bank’s credit risk instead. The bank absorbed the exporting firms’ credit risk at the rate it deemed appropriate in its foreign offices. This risk transformation then allowed the bank to re-sell (“discount”) the debt to others. When bills were discounted in the London money market, each subsequent holder (endorser) also guaranteed the ultimate debt in turn.¹¹ This unique feature of joint liability protected the London money market from asymmetric information with bad bills knowingly traded and passed along.

The multinational banks in this study also had accounts at the Bank of England (BoE), and the BoE only discounted the bills of its own customers.¹² The BoE always

⁸Contemporaries sometimes distinguished the term “banker’s acceptance” from the more general “bills of exchange” to emphasize that the former instrument was backed by a trustworthy financial institution. In this paper, the two terms will be used interchangeably.

⁹For example, “the bill on London enabled the banks [...] to finance a large share of international trade regardless of whether that trade touched Britain’s shores,” (Orbell, 2017, p. 8), and “wines from France, coffee from Brazil, sugar from the West Indies, and silk from Hong Kong were paid alike with bills on London,” (Jenks, 1927, p. 69).

¹⁰However, it is impossible to rule out that they were not also providing other sorts of financing that indirectly impacted international trade. Appendix section C.1 provides more qualitative descriptions of these banks’ businesses.

¹¹King, in *History of the London Discount Market*, describes it as: “a bill of exchange is therefore something more than an acknowledgement of a debt: it is a legally binding undertaking to pay the debt, which is guaranteed by all ‘parties’ to the bill—the acceptor, drawer, and endorser(s). It is, moreover, indisputable evidence that the debt exists, and is therefore an instrument upon which a holder can base a legal action, even against parties with whom he has no direct contractual relations,” (King, 1936, p. xvi).

¹²The BoE used a double-entry accounting system, and all bills that went to the BoE’s discount window (whether they were successfully discounted or not) had their attributes recorded in multiple ledgers, including ledgers tracking the obligations of the acceptors and the liquidity needs of the discounters. This system makes it straightforward to verify that only customers with accounts were discounters or acceptors.

held bills to maturity, so it would ultimately absorb the losses if the original borrower (the exporting firm), the original lender (the British bank), *and* the previous endorsers of the bill all defaulted. Since the BoE was still a firm whose banking operations profited its shareholders, the BoE strictly monitored the quality of its assets.¹³ In addition to using a bill’s history to ascertain its quality, the BoE also monitored its customers’ ability to meet their acceptance liabilities. These many layers of precautions in conjunction with joint liability meant that the bills discountable at the BoE were the safest short-term assets in financial markets with banks unable to strategically offload bad bills at the BoE.¹⁴

Bills of exchange originating abroad to finance international trade were remitted to London where the demand for short-term, safe, liquid assets fueled the second half of a bill’s life-cycle in the world’s largest money market.¹⁵ Discounting the bills from abroad allowed the head office to supply the foreign offices with fresh capital in return.¹⁶ Figure C1 documents the full life cycle of a bill of exchange, and Appendix C.1 provides more detail.

II.B London banking crisis of 1866

The 1866 crisis was the first modern global banking crisis and one of the most severe to ever affect the London money market, during which 21 out of 128 multinational banks headquartered in London stopped operations.

The crisis was caused by the unanticipated bankruptcy of the firm Overend & Gurney, the largest and most prestigious interbank lender in the City of London. Its business as an intermediary, strictly speaking, was restricted to the safe business of buying and selling liquid, short-term bills of exchange from and to London banks. It did not lend long-term on illiquid assets, and it had no overseas operations. It also did not finance trade and had no exposure to overseas exports markets.

¹³The gold standard was maintained by a completely separate set of operations, so bad debts in the Banking Department could not simply be inflated away by printing money in the Issue Department. There is a large literature on the history of the BoE’s transition from a purely private entity to a modern central bank (e.g. Clapham (1945); Capie (2004); Kynaston (2020)). However, the principle that Bagehot (1873) outlined that the BoE (and central banks more generally) would combat moral hazard by only discounting the highest quality collateral remained in place throughout the 19th and 20th centuries.

¹⁴Bignon et al. (2012) calculates the “amount at risk” on the Bank of England’s balance sheet over three crises in the 19th century, and they show that the BoE was careful to limit this amount from any given lender. I also use the BoE’s profit/loss statements to show that the BoE did not suffer losses from its discount window following these crises.

¹⁵The safety and liquidity features of these commercial bills made them the safe assets of this era, much as Treasury bills are today (Xu, 2019).

¹⁶The Eastern Exchange Bank described this cycle of financing between its headquarters in London and its office in Alexandria during its bi-annual meeting on March 1, 1865 the following way: “The bills sent home from Alexandria for correction had to be re-discounted in the Liverpool and London market at the current rates, so as to turn them into gold and send them out to Alexandria to be employed in fresh operations.”

Overend's business had been built over decades by earlier generations of partners such that by the mid-19th century, it was one of the most reputable firms in London. In the early 1860s, a younger generation of partners took over the firm and delegated the business to "wily sycophants" who mismanaged the firm's assets with speculative and illiquid investments that quickly began to fail (King, 1936, p. 246). However, the true state of affairs was not known to the public, and in July 1865 the firm successfully raised equity and converted to a publicly-listed joint-stock firm in a gamble for resurrection. *Banker's Magazine*, a leading financial market publication, fully endorsed the firm and its equity issuance. Soon after, Overend's shares were trading at almost a 100% premium (King, 1936, p. 239). Yet the new capital was not sufficient, and less than one year later on May 10, Overend announced its bankruptcy.¹⁷ After its failure, the shareholders sued the directors for fraudulently misleading them about the true state of affairs in the prospectus. I provide details on the company's history, evidence on shareholders' ignorance of the true state of affairs, arguments presented in the court case, and previous scholarship on Overend in Appendix C.2.

As in the collapse of Lehman Brothers in 2008, Overend's failure led to widespread panic and a flight to safety. *Banker's Magazine* wrote, "It is impossible to describe the terror and anxiety which took possession of men's minds [...] a run immediately commenced upon all the banks, the magnitude of which [...] can hardly be conceived."¹⁸ The money market was completely frozen, and the BoE Discount Window was the only source of liquidity.¹⁹ The BoE was constrained by the gold standard from freely printing notes so it could only meet the liquidity demands with its own reserves, and the panic was fueled by concerns that the reserves would be drained.²⁰ Eventually the BoE obtained permission from the Exchequer to suspend the gold standard and to meet liquidity demands with unbacked notes if necessary, which ended the bank runs.²¹

¹⁷The proximate cause for bankruptcy that necessitated the loan was a court decision that ruled that Overend & Gurney could not collect from a debtor (Sowerbutts et al., 2016). Overend's directors had approached the BoE for a private loan, but the BoE declined to extend credit, claiming that Overend was insolvent. However, the relationship between the BoE and Overend had been contentious since Overend staged a mini run on the BoE in April, 1860, and some scholars believe that this was the true reason their request was rejected Sowerbutts et al. (2016).

¹⁸Appendix C.3.1 provides many additional examples of contemporary newspaper reports of the crisis.

¹⁹"It was impossible to sell either Consols or Exchequer bills, while jobbers in most other securities refused to deal throughout the day [...] Open market discounts were unobtainable," (King, 1936, p. 243).

²⁰The Bank Act of 1844 began the process of consolidating the money supply in the BoE and allowed it a limited fiduciary issue, after which all notes were backed 1:1 in gold. During panics, demand for liquidity quickly drew down the BoE's reserves, after which the gold constraint would bind.

²¹The full text of the letters exchanged on May 11 are in Appendix C.2. In them, the Chancellor of the Exchequer Gladstone emphasizes that his reason for allowing the suspension is because this crisis was purely financial and *not* a commercial crisis. Walter Bagehot, the editor of *The Economist* blamed the severity of the crisis on the BoE's lack of communication about its true willingness to act as a lender of last resort. He wrote, "either shut the [BoE] at once [...] or lend freely, boldly, and so that the public will feel you mean to go on lending. To lend a great deal, and not give the public confidence that you will lend sufficiently and

The crisis in London was also widely reported around the world (see Appendix C.3.2) with the English language newspaper in Buenos Aires writing for example, “an alarming financial crisis has burst in England, threatening widespread misfortune [...] it is certain to affect all parts of the world in commercial relations.” In addition to the dislocation generated by the immediate panic, the BoE kept its discount rate at a punitive 10% for over three months afterwards, which further hindered recovery by making it difficult for banks to re-capitalize and was deeply criticized by contemporaries (Schneider, 2021).²²

Ultimately, 21 banks headquartered in London were forced to close or indefinitely suspend operations. Headquarter closures caused branches abroad to close immediately since they relied on the capital from London.²³

III. DATA

This paper combines several newly collected and digitized historical datasets, and this section gives an overview of the most important datasets and variables constructed. I provide further detail in Appendix H.

III.A Bank characteristics

Lending pre-crisis: The Bank of England kept detailed records of every transaction that occurred at its Discount Window.²⁴ I use the ledgers from 1865–1866 to build a dataset of over 11,000 individual loans from the 128 banks that had international operations in the year before the crisis.²⁵ All banks are headquartered in London and most had both domestic and

effectually, is the worst of all policies, but it is the policy now pursued.”

²²Schneider writes, “The Bank’s discount policy [...] in the general atmosphere of panic and suspicion, had the consequence of forcing even solvent houses to their knees.”

²³For example, the Commercial Bank failed in London May 15. The headquarter’s telegraph to its Bombay offices arrived on May 24 and read, “This bank suspended. Cease all operations. Make no payments. Allow no transfers or sales.” While these branches were directed by the local branch manager, who had wide latitude in daily decisions due to the communication lags with London, they relied on regular fresh injections of capital from London to operate. Unlike in the modern context where branches and subsidiaries have very different structures that have implications for risk-sharing (Fillat et al., 2018), the historical operations were a mix between the two: capital was shared, as in a branch system, but decisions were local, as in a subsidiary system.

²⁴I consider the bills discounted at the BoE during the crisis to be a representative sample of the universe of loans extended by British banks in locations around the world just before the crisis. I provide further explanation and evidence in Appendix C.5.

²⁵For the entries from 1866, I only include bills that originated before the crisis so that the shares are not calculated using any loans that may reflect a post-crisis reallocation of credit. As robustness, I can further restrict the banks’ portfolios to only bills discounted in May 1866 (but originated before then) during the height of the panic when all banks were using the discount window. The results are very similar, and the full discussion is in Appendix C.5.

international operations.

For each handwritten loan record, I document the bank that originated and guaranteed the loan, the city the loan was extended in, the amount, the bank that brought the bill in to be discounted, and the date it was brought to the Bank of England.²⁶ These data allow me to calculate the share of financing by each bank in each city before the crisis.

Bank health: Individual bank failures were reported extensively in contemporary newspapers and recorded by the BoE in internal records. I gathered balance sheets and narrative evidence of the banks' risk-taking and financial health from transcripts of the bi-annual meetings of shareholders at the closest meeting before, during, and after the crisis for publicly traded bank. Names of the managers, directors, and partners of the banks were listed in financial almanacs, advertised in contemporary newspapers, and often mentioned in shareholder meetings.

III.B Exports

Port-level: I measure shipping activity for ports outside the United Kingdom using the daily publications of the *Lloyd's List* newspaper for a two-year window around the crisis. *Lloyd's List* is unique for providing a within-year, within-country measure of exports for the whole world, which makes port-level analysis possible.²⁷ Drawbacks are that it does not report values of the goods onboard and is a British publication that may have a British bias, but there is a strong positive correlation between the number of ships leaving a country in a year and the total value of the country's exports, shown in Figure B2. I provide additional robustness checks for this concern about mismeasurement in Appendix G.1.5.

There are over 400,000 unique shipping events that I digitized, geocoded, and aggregated to generate measures of exporting activity before and after the crisis.²⁸ The dataset has two periods that aggregates shipping for the one year before and after May 1866.

I build several panels, each with two periods: the first aggregates total exports and number of destinations from each country; the second aggregates total exports and number of destinations from each port; and the third panel captures bilateral trade between origin ports and destination countries. In all of these, I restrict the set of ports to those active in

²⁶An example of a ledger page is shown in Figure B1a. Deciphering the handwriting was not trivial. When there was uncertainty about the city of origination, I looked for other loans extended to the same borrower to compare entries. I was able to identify the location and geocode 99.7% of the value of loans.

²⁷While it is technically possible to digitize the *Lloyd's List* for the long-run analysis from 1850–1914, the scale of data collection required is beyond the scope of this paper. An example of this source from September 5, 1866 is shown in Figure B1b.

²⁸Origin ports and destinations are listed very precisely, so they are aggregated into larger units. Different parts of the same port were often named separately, and destinations are inconsistently listed as countries or cities. Ports within 10 kilometers of each other are aggregated into one unit and destinations are countries.

both the pre- and post-crisis periods. I also build a dataset that includes the ports that were ever active in the two periods, which allows me to measure entry and exit. Figure 1b maps the pre-crisis distribution of exporting activity measured by the number of ships.

Country-level: I assemble and standardize the country-level panel of bilateral trade values for 1850–1914 from publicly available datasets of historical trade statistics plus my own contributions. I define countries across datasets as the smallest landmass unit that is consistently reported over all the years.

I collect data on the product-level composition of total exports by country for 1865 and assign them to two-digit SITC codes to capture the pre-crisis industrial composition.²⁹

IV. EMPIRICAL STRATEGY

The goal of my empirical analysis is to estimate the causal relationship between the supply of financing in a location and its exporting activity. I relate the log of exports EX_l at location l to the log of the amount of financing in a given period, $Finance_l$, measured by loan volumes:

$$\ln(EX_l) = \alpha + \gamma \ln(Finance_l) + \Gamma'X_l + \varepsilon_l \quad (1)$$

Identifying γ from Equation 1 is challenging for two reasons. First, observed financing is an equilibrium outcome that conflates supply and demand, so places that demand less financing are also likely to have less trade. Equation 1 will therefore not satisfy the orthogonality conditions that $E[Finance_l \varepsilon_l] = 0$ since ε_l includes the unobserved local economic conditions that are positively correlated with finance that biases γ upward. Second, there might be reverse causality: firms in locations that are already less productive can weaken their banks' balance sheets through non-performing loans and cause those banks to contract their lending or even to fail.

I overcome these challenges by combining the unique dataset of the cross-section of multinational British bank lending with the institutional structure where branch offices depended directly on their headquarter's ability to provide capital. Banks whose headquarters in London failed due to the panic generate plausibly exogenous variation for their branch locations' exposure to bank failures, and therefore to the supply of bank financing.

²⁹Historical data on bilateral trade flows disaggregated by industry and year is unavailable for most countries and has mostly not been systematically collected.

IV.A Measuring the exposure to bank failures

Bank shocks are captured by the binary variable $\mathbb{I}(Failure_b)$ that takes the value 1 if the bank failed in 1866 and 0 otherwise. A location l 's dependence on each bank b is measured as bank b 's share of financing in location l : $z_{lb} = \frac{Finance_{lb}}{Finance_l}$, measured in the pre-crisis period. These shares sum to 1 in each location. The dot product of these two terms gives each location's exposure to bank failure $Fail_l$:

$$Fail_l = \sum_b z_{lb,pre} \times \mathbb{I}(Failure_b) \quad (2)$$

$Fail_l$ takes the form of a Bartik instrument where the pre-crisis importance of each bank to a location ($z_{lb,pre}$) are the "shares," the bank failure rates are the "shocks," and financing ($Finance_l$) is the endogenous variable. It is continuously measured from zero to one. I provide the derivation of the instrument in Appendix D and discuss instrument validity in Section IV.B.

I estimate the following reduced form relationship between exposure to bank failures and log exports:

$$\ln(EX_{lt}) = \beta(Fail_l \times Post_t) + \Gamma' X_{lt} + \varepsilon_{lt} \quad (3)$$

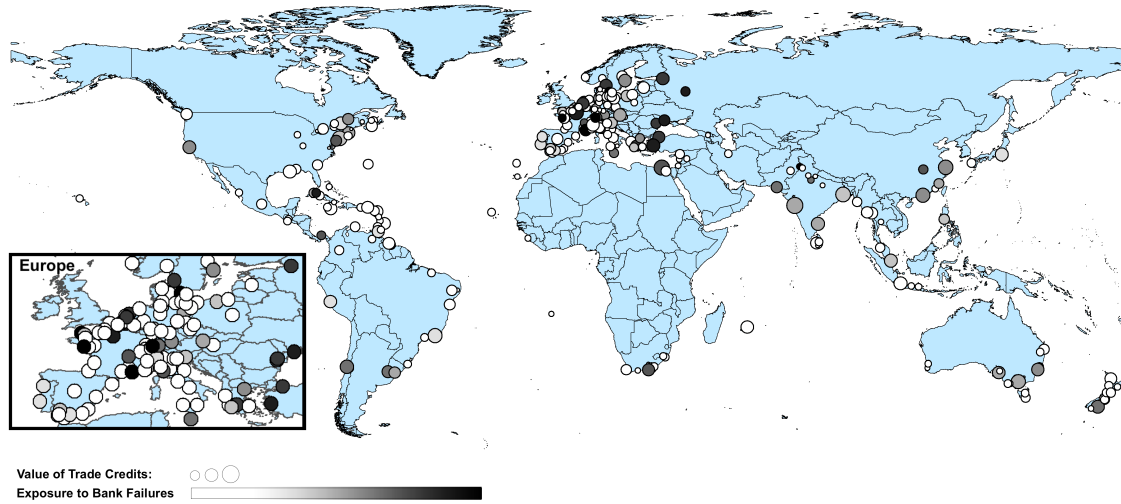

The coefficient β in Equation 3 is the reduced form semi-elasticity of the response of trade activity to British bank failures in location l in the post-crisis ($Post_t$) period.³⁰ Note that estimating the reduced form relationship means it is not possible to distinguish between the many different roles of banking activity, such as credit provision or risk assessment. Given the historical evidence of these banks' role as mostly providers of trade financing, this "trade finance channel" is likely important, but other forms of banking activity that impacts exporters would also be affected by bank failures and captured by β .

Figure Ia maps the geographic distribution of exposure to bank failures, $Fail_l$ at the city level. The size of the points measures the pre-crisis amount of British lending in the city, and the color denotes the bank failure share. This map shows within and across-country variation in failure rates. Figure B4 plots the distributions of exposure across ports and countries and shows representation across the entire range. Table I reports the descriptive statistics for ports and countries in 1865. The average port had 119 ships leaving in the pre-crisis period and 7 pp exposure to failed banks. The average country exported £12.2 million and was exposed to 9 pp bank failures.

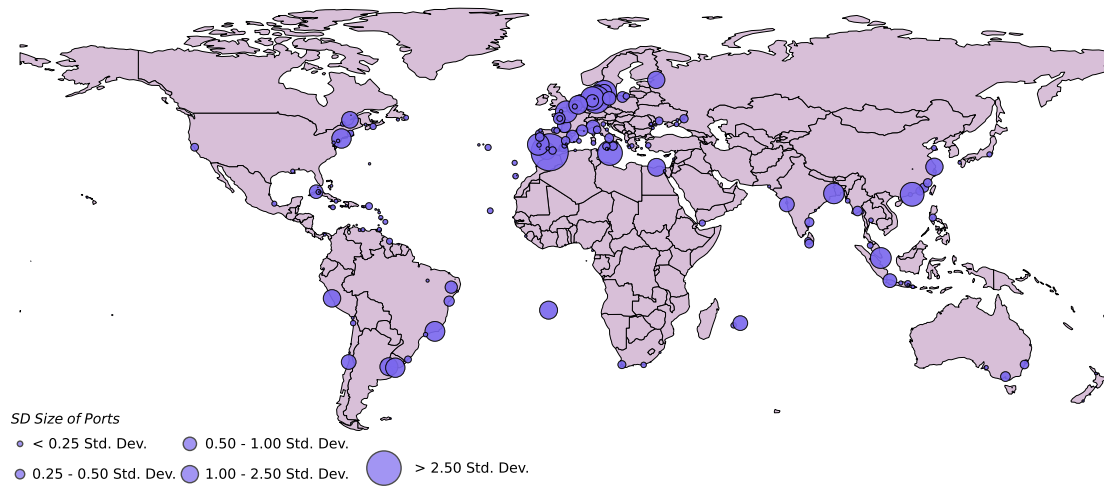

³⁰Data limitations prevent estimating the full first stage. I estimate a pseudo first stage with the available data in Table A1, which is representative of all banks (Table A2). I provide more details in Appendix A.

FIGURE I: Geography of banking and trade

(a) British multinational bank lending and failures

(b) Port-level trade activity

Notes: Figure Ia maps the distribution of the city-level exposure to bank failures $Fail_i$. The size of the points denote the log value of total credit at each city and the color gradient denotes the exposure to failure, ranging from 0 to 1. Figure Ib maps the distribution of shipping activity at ports in the pre-crisis year. The size of the points denote the log number of ships leaving. Ports in the United Kingdom are not included. Source: *Lloyd's List*.

TABLE I: Summary statistics: ports and countries

	Ports			Countries		
	mean	median	sd	mean	median	sd
Exposure to failed British banks	0.07	0.00	(0.19)	0.09	0.03	(0.14)
Exports	118.76	27.00	(215.53)	12.20	2.14	(31.89)
Share exports to UK	0.39	0.30	(0.34)	0.60	0.69	(0.38)
Destinations (# countries)	7.63	5.00	(7.21)	3.85	2.00	(8.06)
Distance to destination (km k)	5.06	4.80	(3.31)	6.52	6.31	(3.51)
British banks	6.03	3.00	(7.54)	13.45	9.00	(13.82)
Non-British banks	0.45	0.00	(0.82)	1.26	0.00	(3.25)
Fraction in British Empire	0.34	0.00	(0.47)	0.33	0.00	(0.47)
N	289			55		

Notes: Table I shows summary statistics from the port-level panel of shipping activity and the country-level panel of values of exports. All variables are measured at the end of 1865, before the crisis. “Exports” is measured by the number of ships departing for ports, and by the value of exports in millions of pounds sterling for countries. Share of exports to the UK is similarly calculated using the number of ships and values of exports.

IV.B Validity of the reduced form estimation

The reduced form relationship in Equation 3 will identify the effect of contractions in bank finance on exports if $Fail_l$ satisfies the standard exclusion restriction: $E[Fail_l \varepsilon_l] = E[\sum_b z_{lb} \mathbb{I}(Failure_{e_b}) \varepsilon_l] = 0$. The equation is immediately satisfied if bank failures are randomly assigned, but it does not require it.

The less restrictive requirement is that the instrument will be valid if the bank-level shocks are uncorrelated with the average location-level characteristics that determine exporting activity (Borusyak et al., 2022). The identifying assumption is that banks did not sort to locations such that location characteristics were correlated with both failures of the British multinational banks operating there and declines in exports in 1866.³¹ One example of problematic sorting would be if banks that failed systematically operated in locations that experienced a boom pre-crisis and a bust post-1866. Declines in exports and failures of the banks operating in those locations would coincide and be falsely attributed to the London crisis. However, to the extent that indicators of a boom and bust cycle are observable, it is possible to test for systematic sorting to address this concern.

³¹Borusyak and Hull (2020) discuss issues arising from non-random exposure to shocks even in the case of linear instruments, but those concerns do not apply to this setting because the shares sum to 1.

IV.C Determinants of bank failures

Quantitative measures & narrative evidence

Banks are balanced across most observable pre-crisis bank characteristics (Table II). Panel A lists publicly-held banks (“joint-stock” banks) that published balance sheets. The characteristics of the banks that failed are not statistically or economically different from those of banks that did not fail along all dimensions: equity capital, equity already paid in by shareholders, reserve funds, deposit liabilities, total size, leverage ratio, liquidity ratio, and reserve ratio.

I also analyze transcripts of the banks’ bi-annual shareholder meetings that cover their operations from 1865 to 1867, which provide qualitative evidence on the nature of each bank’s business. There is no evidence that differences in local economic conditions or bank risk-taking behavior affected their failure rates. The full results, discussion of the sources, and examples of the language are in Appendix C.6.

Panel B includes all banks and their other observable characteristics. Banks that survived were older by 27 years (half a standard deviation), but age would only be a confounder if older banks systematically operated in locations that are both exposed to bank failures and less likely to experience declines in exports. Geographical region of specialization is also not systematically different and does not predict bank failure, measured either in nominal values (Panel B) or as a share of the bank’s assets (Table A3). Banks in the two groups are similarly geographically diversified, operating in an average of almost 14 cities and 7 countries. This balance helps to address the concern that bank failures and export contractions were simultaneously caused by a shock that was systematically correlated with their geography, such as adverse weather.

Overend & Gurney connection

The primary explanation for why some banks failed appears to be a public connection to Overend & Gurney. As was standard at the time, investors had only “paid in” a fraction of their equity and could be “called” for the remainder.³² The shareholder list circulated in London at 2.5 times the publishing price during the crisis, and contemporary evidence indicates that depositors found this a valuable piece of information.³³

I digitize the shareholder list from January 1866 (Figure C2a) and compare it to

³²Specifically, they had only paid in £15 of the £50 nominal and could be obligated for the remaining £35 per share at any moment. £35 in 1866 is equivalent to £4,193 in 2020.

³³See Appendix C.3 for contemporary documentation of the crisis and the demand for the shareholder list.

Notes: Table II Panels A and B shows bank-level balance across characteristics for banks that failed and did not fail. All variables are measured at the end of 1865 before the crisis. Balance sheet variables were only published for publicly traded banks; these are reported separately in Panel A. “Not Failed” and “Failed” refers to whether a bank suspended or closed during the crisis. Means are reported first, and standard deviations are given in parentheses. “Diff” refers to the difference in means between groups. Standard errors are reported in parentheses for the “Diff” column. £k denotes units of thousands of pounds sterling. £m denotes units of millions of pounds sterling. Leverage ratio is defined as capital (paid and reserves) divided by total assets. Reserve ratio is defined as reserve assets divided by deposit liabilities. Liquidity ratio is defined as cash, gold, and short-term bills divided by total assets. “Cities,” “Countries,” and “Regions” count the number of unique egeographic locations banks operate in. Significance is marked by * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. *Sources:* Bank of England Archives C24/1, *Banker’s Magazine*, *The Economist*.

the names of the managers and directors of the London banks (Figure C2b).³⁴ A bank is characterized as having a known connection to Overend & Gurney if one of its managers or directors is listed as a shareholder. It is reasonable that upon observing this public connection to a failed, fraudulent firm, depositors lowered their assessments of their bankers' investment decisions which worsened the runs on those institutions. Table II Panel B row 1 shows that this public Overend connection significantly predicts bank failure (Panel A row 1 shows this relationship is even stronger for joint-stock banks, which more heavily advertised the identities of their managers and directors). Moreover, there is little correlation between the Overend connection and the observable characteristics of either bank age or bank lending patterns (Table C2).³⁵

IV.D Correlation between location characteristics and bank failures

To test the exogeneity of bank-level failure rates to location-level characteristics, I follow Borusyak et al. (2022) and calculate each bank's exposure to those characteristics and correlate them with the bank failure rates.³⁶

I examine the observable pre-crisis location-level characteristics at both the port-level and the country-level, since those are the two units of observation in the analysis. At the port-level, the observable characteristics include the volume of exports (proxied by the number of ships from the *Lloyd's List*), importance of the United Kingdom as a destination, geodesic distance to London, latitude, number of destinations, availability of non-British financing, and whether the port is a capital city.³⁷ At the country-level, observable characteristics include total value of exports, exports growth rates pre-crisis, value of exports by industry, share of commodities in the composition of exports, monetary system, and whether the country was engaged in conflict. Each bank's share-weighted average exposure \bar{X}_b to these

³⁴The shareholder list was found at the Royal Bank of Scotland archives in Edinburgh, Scotland. January, 1866 was the last list that was compiled before the firm declared bankruptcy.

³⁵Overend's ledgers do not appear to have survived, so it is not possible to calculate each bank's operational exposure to the firm. However, since the primary business banks had with Overend was buying and selling bills—a transaction that was cleared immediately without any liabilities being held on the balance sheet—Overend's failure would not have directly impacted their books. In addition, shareholders eventually covered all of Overend's debts in full, and the extent of operational relationships was not known to the public.

³⁶The advantage of testing the bank-level relationship rather than the location-level relationship, the latter of which is also used in the literature, is that it performs the Adao et al. (2019) standard error correction. They show that when the source of identification from a Bartik instrument are the shocks, the standard errors of regressions of the instrument on location characteristics tend to over-reject the null hypothesis. Intuitively, the location-level tests target randomness in the shares, but when the location shares themselves are not suitable instruments, the covariance between the shocks and the shares may be relevant. Borusyak et al. (2022) show that implementing the Adao et al. (2019) standard error correction is equivalent to translating the location-level characteristics into bank-level exposure rates.

³⁷Results are similar using sailing distance instead of geodesic distance to London. Figure B5 shows the strong positive correlation between the two types of distances.

pre-crisis characteristic X_l is calculated as $\bar{X}_b = \frac{\sum_l z_{lb} \times X_l}{\sum_l z_{lb}}$ where larger weights are given to locations more dependent on bank b . The normalized individual bank failure rates are regressed on the transformed location-level characteristics \bar{X}_b :³⁸

$$\mathbb{I}(Failure_b) = \alpha + \beta \bar{X}_b + \varepsilon_b \quad (4)$$

Table III reports the results and shows that there is balance on almost all characteristics. In terms of port-level characteristics, Panel A shows that two factors are unbalanced: banks operating in ports with a higher fraction of exports going to the UK were more likely to fail, and those operating in ports that were also the capital cities within countries were less likely to fail. These characteristics are included as controls in the baseline specifications to residualize any direct effect that they have on exports.

Table III Panel B shows that banks that failed did not systematically operate in countries with lower exports values, higher pre-crisis exports growth rates, a greater share of trade to the UK, or exposure to military conflicts and different monetary standards.

In order to address the possibility of commodity booms and busts, I categorize each country's 1865 exports by two-digit SITC categories and test balance across all industries and to the overall share of commodities exported. Table III Panel C shows that banks that failed are not differentially exposed to the top seven industries of raw cotton exports, cotton manufactured goods, all cotton, bullion, grains, coffee, alcohol, and the overall share of commodities exported. In Table G16, I provide balance checks for remaining SITC industries. Finally, I check that these characteristics are not jointly significant (Figure B3) and find an F-stat of 1.14 with a p-value of 0.32.

³⁸The regressions are weighted by \hat{z}_b , which is the average location exposure to bank b : $\hat{z}_b = \frac{1}{L} \sum_{l=1}^L z_{lb}$. The weighting is necessary to translate location-level relationships to bank-level relationships. The full derivation for the equivalence is given in Borusyak et al. (2022).

Notes: Table III reports estimates from the bank-level regression of bank exposure to location characteristics pre-crisis on bank failure rates. The dependent variable is $\mathbb{I}(\text{Failure}_b)$, the measure of bank failure. The independent variable of interest \bar{X}_b is the share-weighted exposure of banks to location characteristics, normalized to have zero mean and unit variance. Each column is labeled with the independent variable. The coefficients are interpreted as the increase in the probability that a bank fails given a standard deviation increase in the average bank exposure to a particular characteristic. Panel A includes location characteristics from the port panel. Panels B and C includes country-level characteristics like the monetary standard and presence of conflict in the exporting country in 1865/1866, and the industry composition of exports in 1865. The effective sample size is the inverse of the HHI of shock-level average exposure: $\frac{1}{\sum_b z_b^2}$ and is equal to 27.55 for ports and 28.05 for countries. Regressions are weighted by the average location's exposure to bank b . * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$

As discussed in Borusyak et al. (2022), another advantage of transforming the balance tests into shock-level (bank-level) regressions is that it makes it clear which shocks (banks) are the most relevant for the results. In Panel A columns 1–8, there are 122 observations instead of the full 128 because 6 banks operated in cities which were not the closest city for any port, so they do not contribute to the port-level exposure measures.

V. RESULTS

V.A Conceptual framework

The conceptual framework tying financial constraints to persistent changes in export dynamics relies on two main assumptions: a sunk cost of entry and substitutability among producers.³⁹ The sunk cost of establishing a trade relationship with a given destination (which cannot be recovered if the exporter exits) covers expenses such as learning about the local market and setting up communication and distribution networks.

Given the institutional framework of bank-intermediated trade financing where exporters need to cover working capital costs during the period of a shipment, I add external financing as a marginal cost to a Melitz (2003) framework.⁴⁰ Firm profits are an increasing function of productivity, financing supply in the exporter's location, and inverse trade costs. Appendix E contains the details of the model, discussion, and extensions.

In this framework, a financing shock lowers the supply of financing, which raises exporters' prices, lowers their profits, and raises the overall price index in their destinations. Exposed exporters will (1) export less (because their prices have increased) and (2) be less likely to enter new markets (because they are less profitable). They may not exit a market because re-entry in the future will require paying the sunk costs again, so there is an option value to continuing to export even with negative flow profits.⁴¹

In a destination, importers will indirectly experience their trade partners' financing shock through an increase in their own price index. Higher price indices raise average profits, and (3) new firms will enter a destination and increase the number of relationships importers have. Post-shock, the competitive entry plus lack of exit means that the mass of firms operating is higher, making future entry more difficult. In an environment with high

³⁹In the classic Baldwin (1988) framework, firms produce a homogeneous good and are completely substitutable. In Redding et al. (2011) the possibility of multiple equilibria is expressed as a function of how similar (and profitable) each potential location is for an industry. In spatial geography models (Krugman, 1991; Davis and Weinstein, 2008; Allen and Donaldson, 2020), persistence (or multiple equilibria) arises out of agglomeration forces. In all cases, large enough shocks can shift the equilibrium, either due to sunk costs investments or by allowing the agglomeration forces to entrench elsewhere.

⁴⁰Chaney (2016) and Manova (2013) also both adapt Melitz (2003) to incorporate financing shocks, where the former assumes that the liquidity necessary to export is randomly drawn and uncorrelated with firm productivity while the latter ties firm borrowing constraints to firm productivity through default risks. In both cases, financing is only necessary to pay for entry costs, and imperfect financial markets constrains some firms that are productive enough to export from doing so.

⁴¹Note that if exporters are only exposed to a recurring fixed cost, the financing shock will also increase the likelihood of exit. The presence of sunk costs is also the friction that generates hysteresis in exporting status in Roberts and Tybout (1997) and in the geographic distribution of industrial activity in Redding et al. (2011).

substitutability and switching costs, (4) the market share losses can persist.⁴²

Following Redding and Weinstein (2017), the underlying firm-level dynamics described in the conceptual framework can be aggregated and then analyzed using more macro measurements of trade. Appendix E provides more discussion of this point.

V.B Immediate effects

Intensive margin

I examine the immediate impact of bank failures on the intensive margin of exports with the *Lloyd's List* panel and restrict the analysis to locations that are active both before and after the shock in the two-year window around the crisis.

First, using the country-level panel, I estimate the following difference-in-differences regression with continuous treatment intensity:

$$\ln(S_{ot}) = \beta (Fail_o \times Post_t) + \gamma_o + \Gamma' X_o \times Post_t + \varepsilon_{ot} \quad (5)$$

S_{ot} is the total number of ships departing a country per period. β is the coefficient of interest, and $Fail_o$ is an exporting country's exposure to bank failures calculated according to Equation 2 using country-level shares of pre-crisis bank dependence. $Post_t$ is an indicator for the post-crisis period that controls for macroeconomic shocks affecting the export trends over time. X_o are pre-crisis country characteristics that can be included as additional controls when interacted with $Post_t$. Country fixed effects γ_o absorb all time-invariant differences in levels of shipping, including those correlated with their exposure to bank failures. Regressions are weighted by the pre-crisis size of country-level shipping activity. Standard errors are clustered by country of origin.

Table IV column 1 shows the baseline effect without any additional country-level controls. The coefficient of -0.61 implies that countries with an average exposure of 9 pp exported 5.4% less than non-exposed countries in the post-crisis year. Table A4 adds origin-country characteristics as controls to show that the results are not affected by differences in macroeconomic characteristics, such as the industry composition of exports.

It is possible that unobserved country-level shocks are partly accounting for the results, so next I identify the effects using within-country variation from port-level shipping

⁴²In addition, exporters learn about their trade partners, become more productive, and direct their investments to accommodate demand so early movers accumulate advantages. There is much empirical evidence that the quality and value of trade relationships improves over time with learning. In the context of the 19th century Juhász and Steinwender (2019) document that agreeing on the specific goods traded is a costly process while in a modern context, Atkin et al. (2017) show that the process of exporting itself improves firm productivity through learning-by-doing.

activity that allows me to control for unobserved time-varying shocks to the origin-country. To do so, I estimate the port-level analogue to Equation 5 where S is now the number of ships leaving from port p in origin country o in period t :

$$\ln(S_{pot}) = \beta(Fail_{po} \times Post_t) + \Gamma' X_{po} \times Post_t + \alpha_p + \gamma_{ot} + \varepsilon_{pot} \quad (6)$$

Each port in the panel is matched to the closest city of financing by geodesic distance, and its exposure to bank failures $Fail_{po}$ is assumed to come from that city.⁴³ Ports more than 500 km from the nearest city of financing are part of a control group of completely unexposed ports and are given an exposure of zero.⁴⁴ This control group allows for ports that are still connected to London but experienced no bank failures to react differently from ports that were not connected to London at all. X_{po} are pre-crisis port characteristics that can be included as additional controls. Port fixed effects α_p absorb all time-invariant port-specific differences in levels of shipping, and origin-country-by-post fixed effects γ_{ot} flexibly control for all observed and unobserved changes at the country-level that affect shipping, such as GDP and multilateral resistance.⁴⁵ Including these fixed effects means β is identified by comparing ports from the same country and year.⁴⁶ Standard errors are clustered by the country of origin to allow for heteroskedasticity and within-country spatial correlations.

Table IV columns 2–4 presents the baseline results with fixed effects and controls added sequentially. The country-by-post fixed effect does not significantly impact magnitudes, indicating that there were unlikely short-term country-level shocks correlated with both exposure and exports. The additional controls are based on the port-level characteristics that are not balanced between banks that failed and did not fail in Table III and include the average age of the banks, the Overend & Gurney connection, whether the port is the capital city, and the share- of ships going to the UK in the pre-crisis year.⁴⁷ The coefficient of -0.66 in column 4 with all the controls indicates that ports with an average exposure of 7 pp have 4.6% lower exports in the post-crisis year. These magnitudes are very similar to the country-level estimates (Column 1) which provides further evidence that banking failures

⁴³For example, the port of Piraeus in Greece is designated as receiving its funding from Athens.

⁴⁴I include an indicator for these ports interacted with the post time period. The results are not sensitive to the 500 kilometer boundary and the main coefficients are robust for a range of distances and to not including the time-varying intercept for distant ports.

⁴⁵Assuming that all other relevant trade costs that countries face vary at the country-level, these fixed effects will absorb changes in the multilateral resistance that countries experience in general equilibrium.

⁴⁶There are on average 5 ports per country. Countries with only one port are effectively dropped from this estimation. These account for 8 of the 289 ports (2.8 percent), which reduces the effective number of countries in the estimation from 54 to 46.

⁴⁷Bank-level characteristics are aggregated to the port-level using the pre-crisis shares $z_{lb,pre}$ of the importance of each bank to each location.

are orthogonal to country-level characteristics that would have changed the path of exports.

In Table G1, I add each control variable in turn and show that the coefficients remain stable and statistically significant. I also implement the recommended bounds in Oster (2019) to show that selection on location-level unobservable characteristics is minimal. These calculations show that the degree of unobservables bias would have to be approximately 40 times larger than the degree of observables bias. The $Fail_{po}$ measure is skewed so in Table G4, I provide a breakdown of the effect by terciles.

Table IV columns 5–7 summarize several robustness checks. Column 5 excludes the cotton-exporting countries that may have experienced a correlated shock due to the end of the American Civil War;⁴⁸ column 6 accounts for potential mismeasurement in the outcome variable by re-estimating all the results using count data methods; and column 7 uses the time-series granularity of the *Lloyd's List* and allows for communication lags between London and cities around the world. The estimated effects are very similar across these specifications. Appendix G.1 provides extensions of each result (Table G6 for cotton, G7 for news lags, and G8 for the Poisson estimator). In addition, I show that the baseline effects are robust to controlling for exposure to different regions (Table G2) and empires (Table G3) and are not due to demand shocks both specifically from the UK and more generally (Tables G5 and G9); I limit the sample to well-traveled routes to diminish the impact of outliers along routes (Figure G2, Tables G8 and G10); I remove ports in countries that are islands and entrepôts (Table G11), and I show similarity to annual regressions using country-level values of exports (Table A7).

Extensive margin

To study the extensive margin, I categorize exporting activity in two ways: the first is the number of unique destinations that a port or country trades with conditional on exporting, and the second is the likelihood that a port engages in any international trade.

I can decompose the change in total exports to countries (estimated without any controls) in Table IV column 1 into the change in the number of destinations (Table V column 1) and the change in average exports per destination (Table V column 2). The change in the number of destinations (column 1) is my first measure of extensive margin changes, estimated using the specification in Equation 5. The decomposition shows that while both margins contribute to the drop in total exports, most of the drop is accounted for by the fact that more exposed places end up with relatively fewer trade partners.⁴⁹ Table V

⁴⁸These countries are Brazil, Egypt, India, and the United States.

⁴⁹Note that in a difference-in-differences setting, this result does not necessarily imply a drop in the number of destinations but rather that exposed locations gained relatively fewer in the post-period.

TABLE IV: Intensive margin effect of bank failures on shipping

Col 1: $\ln(S_{ot}) = \beta \text{Fail}_o \times \text{Post}_t + \Gamma' X_o \times \text{Post}_t + \gamma_o + \varepsilon_{ot}$
 Col 2-7: $\ln(S_{pot}) = \beta \text{Fail}_{po} \times \text{Post}_t + \Gamma' X_{po} \times \text{Post}_t + \alpha_p + \gamma_{ot} + \varepsilon_{pot}$

Ports		289	289	289	247	289	289
Clusters	54	54	54	54	50	54	54

Notes: Table IV reports estimates from the difference-in-difference regressions from the two-period panel of port-level shipping activity in the year before and after the crisis. The dependent variable in columns 1–5 and 7 is the log of the total number of ships departing in each period. In column 6, a Poisson estimator is used so the dependent variable is the count of ships. Fail_{po} is the share of the port’s banks that failed during the crisis. The mean of Fail_{po} is 0.07, and the standard deviation is 0.2. Post is a dummy for the post-crisis year that takes the value of 1 after May 1866 and 0 otherwise. The time-invariant control variables are measured in 1865 and interacted with the post dummy. They include an indicator for the port being a capital city within the country, the average age of banks, the fraction of banks with an Overend connection, and the share of shipping to the UK in the pre-shock period. The sample is restricted to ports active in both the pre- and post-period. In column 5 the sample excludes major cotton exporting countries defined as Brazil, Egypt, India, and the United States. In column 7, the “post” crisis period varies at the port-level based on the news arrival dates of the crisis from London. Standard errors in brackets are clustered by country of origin. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$

column 3 shows a similar drop in the number of destinations for ports.

Next, I examine the extensive margin of exporting at all. I expand the sample to include all ports that are present in either the pre- or post-shock periods. I categorize ports as *Entering* into international trade if there is no exporting activity in the pre-crisis period and positive exports in the post-crisis period, and *Exiting* if the reverse is true. I estimate a linear probability model on a one-period cross-section where E_{po} is an indicator for either *Entry* or *Exit* and standard errors are clustered by the origin-country:

$$\Pr(E_{po}) = \alpha + \beta Fail_{po} + \gamma_o + \Gamma' X_{po} + \varepsilon_{po} \quad (7)$$

Table V, columns 4 and 5 present the likelihood of $Entry_{po}$ and of $Exit_{po}$, respectively including all port-level controls. The shock is a statistically significant deterrent to the extensive margin ability to establish links with foreign markets, but it does not significantly impact exit. The differential effects for entry versus exit provide further evidence that sunk costs of establishing relationships were a relevant friction.⁵⁰ Taken together, these results show within and across-country evidence of the financing shock immediately lowering exports, primarily by preventing the extensive margin growth experienced by unexposed countries.

It is worth noting that the extensive margin of trade is sensitive to mismeasurement where very small flows may not be reported. These concerns are bigger with more disaggregated data, and in the context of port-level flows, the *Lloyd's List* may be less accurate for smaller ports. If so, changes on the extensive margin, especially for entry, may not be captured. However, as long as the mismeasurement is not systematically correlated with exposure, this would not be a source of omitted variable bias.

V.C Long-run effects

I turn to the country-level bilateral trade data from 1850–1914 to examine the changes to global trade patterns in the long-run.

Total exports

There is a permanent divergence in the cumulative growth of total exports across countries. In Figure II, I plot the annual aggregate values of exports for countries binned into above and below-average exposure to bank failure, where the average exposure is defined in the

⁵⁰Similarly, Berman and Héricourt (2010) empirically find that access to finance influences the firm entry decision, but that it has no effect on the exit decision. In Chaney (2016), it is the extensive margin of exports that generates changes in aggregate trade flows in response to valuation shocks.

TABLE V: Extensive margin effect of exposure to bank failures

	Con: dest	Con: avg ships	Ports: dest	I(Port Entry)	I(Port Exit)
	(1)	(2)	(3)	(4)	(5)

N	108	108	574	331	318
Ports			289	331	318
Clusters	54	54	54	55	54

Notes: Table V reports estimates of the effect of the exposure to bank failures on the extensive margin of shipping activity. The dependent variable in columns 1 and 3 is the log number of unique destinations accessed by countries and ports, respectively. The dependent variable in column 2 is the log of the average number of ships per destination from a country. The sample in columns 1 to 3 is restricted to ports that were active in both the pre-shock and the post-shock periods. The dependent variable in column 4, I(Port Entry) is a binary variable that takes the value of 1 for a port that was not active in the pre-shock period and became active in the post-shock period, and 0 otherwise. The dependent variable in column 5, I(Port Exit) is a binary variable for a port that was active in the pre-shock period and became inactive in the post-shock period. The sample size in columns 4 and 5 reflect the number of ports that were active in the post-period (for *Entry*) or pre-period (for *Exit*). All variables are defined the same way as in Table IV. Standard errors in brackets are clustered by country of origin. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$

cross-section of countries (9 pp), and levels for each group are indexed to equal one in 1866. The blue line shows the total value of world exports. The overall pattern is of tremendous growth: total global trade increased five-fold over this period. Before 1866, exports are expanding at the same rate between the two groups of countries so there are no differential pre-trends between the groups, but after 1866 there is an immediate divergence in levels that does not recover. Figure B9a graphs the difference between the two groups and Figure B9b plots the coefficients and standard deviations from the equivalent regression (including country and year fixed effects). The coefficients are significantly different from zero and increase in magnitude from 1867–1870, after which they level off at approximately -0.5. These coefficients imply that an exporter with average exposure has 20.6% persistently lower levels of total exports on average than with the unexposed counterfactual.

FIGURE II: Aggregate exports, grouping countries by above and below average exposure to bank failures

Notes: Figure II plots the raw data for the total value of exports by groups of countries from 1850–1914. Countries are binned into two categories: “Below avg failure” refers to countries that experienced below average exposure to bank failures in London, where the average rate was calculated in the cross-section of exporting countries in 1866. “Above avg failure” refers to countries that experienced above average exposure to bank failures. Exports values are normalized to equal 1 in 1866. The vertical line marks 1866.

Bilateral exports and market-share effects

The divergence in total values of exports between more and less exposed countries could be

driven in part by the importing country’s demand. In particular, if more-exposed countries happen to have stronger relationships with countries that experienced slower imports demand growth after the crisis, their exports would be affected. My baseline estimation therefore uses bilateral exports volumes and controls for annual demand shocks from importers:

$$\ln(EX_{odt}) = \beta_t Fail_o + \Gamma' X_{ot} + \gamma_o + \gamma_{dt} + \theta_t \ln(\text{dist})_{od} + \varepsilon_{odt} \quad (8)$$

The dependent variable is the log value of exports EX_{odt} from origin country o to destination country d in year t . $Fail_o$ is the origin-country exposure to bank failure, and it is interacted with leads and lags that estimates the effect pre- and post-shock. X_{ot} includes pre-crisis origin-country characteristics that are interacted with year dummies, which control for macroeconomic differences among countries. Origin-country fixed effects γ_o control for time-invariant country characteristics and restrict the source of variation to the change in exports within each country between periods. As in the port-level estimation, I control for the effect of the origin country not having any British banks at all in 1866, which separates the effect of any exposure from the degree of exposure to failed banks.⁵¹ Destination-country year fixed effects γ_{dt} control for demand shocks by restricting the identifying variation to being across exporters, within-destination-year. I control for the distance between countries dist_{od} measured either geodisically or as the fastest travel time.⁵² I omit the covariate in the baseline year and normalize it to zero. Standard errors are clustered at the unit of treatment, the exporter country.⁵³

I allow β_t to vary annually and at five-year intervals ($[1850, 1855], \dots, [1911, 1914]$). β_t is interpreted as the semi-elasticity of the relative volumes that the average importer buys from more versus less-exposed exporters each period. It is identified using cross-sectional variation in every period, but it uses the full panel of data to control for determinants of trade flows like average country size.

Figures IIIa and IIIb plot the estimated β_t coefficients annually and at five-year intervals, where β_{1866} and β_{1861-5} are the omitted years in each specification respectively. I scale the point estimates and standard errors to reflect the effect for the average level of exposure (9 pp). Figure B7, plots the estimated coefficients at the 25th, 50th, and 75th percentiles of exposure (3 pp, 8 pp, and 18 pp, respectively) conditional on non-zero exposure. Table A8 reports the distribution at various percentiles both conditioning and not conditioning on non-zero exposure. Figure B8 plots the unscaled results, and those point

⁵¹These countries accounted for 2% of the value of exports in 1866 since British banks operated in countries accounting for 98% of world exports.

⁵²I use Pascali (2017) for distance by either sail or steam.

⁵³Results are robust to different ways of clustering as reported in Table A7.

estimates are reported in Table G12 (column 2).

The persistence is striking: destination countries imported significantly less from exporters that had been exposed to bank failures for almost 40 years. $\beta_{1901-05}$ is the first period when the effect is only borderline statistically different from zero. In a two-period estimation with a single post-period, β_{post} is -1.32 log points (standard error 0.42). Given the average exposure of 9 pp, this magnitude implies that the (partial equilibrium) disruption in the shape of global trade was 12% every year in the post-crisis period until WWI.

The estimated coefficients support the patterns in the raw data for total exports that exposure to the crisis had no effect on exports pre-crisis but immediately lowered trade flows between countries afterward. The lack of pre-trends and the balance on observables discussed in Section IV.D helps to address the potential identification concern that stronger banks were systematically better at choosing their operating locations and therefore tended to operate in better places. This sort of selection bias would lead to a pre-trend in the event study difference-in-differences because good places with low exposure would already be growing before 1866, but this is not the case.

Structural gravity

The reduced form specification in Equation 8 estimates the overall effect of the financing shock on exports, which may be operating through either a trade financing channel that only affects exporting or a more general bank lending channel that also affects production for instance. However, assuming that the financing shock acts as a pure trade cost shock makes it possible to estimate a theoretically grounded elasticity arising from structural gravity models that can be compared to other trade costs in the literature. Structural gravity models show that a change in the bilateral trade costs between any two countries will impact all other countries even if everything else remains the same. These multilateral resistance terms are nonlinear functions of the full set of bilateral trade costs and are not directly observable, but using exporter and importer country fixed effects in cross-sectional estimations (e.g., Feenstra, 2016) or exporter-year and importer-year fixed effects with panel data (Olivero and Yotov, 2012; Head and Mayer, 2014) delivers consistent estimations.

Equation 8 differs from the fixed effects implementation of structural gravity because I cannot include origin-country-year fixed effects, as those are collinear with treatment. I therefore follow the technique introduced by Baier and Bergstrand (2009) and implemented in Berger et al. (2013), which approximates the nonlinear multilateral resistance terms with a first-order log-linear Taylor series expansion. This technique imposes additional restrictions

FIGURE III: Persistent effect of financing shock on exporter market share

$$\ln(\text{EX}_{odt}) = \beta_t \text{Fail}_o + \Gamma' X_{ot} + \gamma_o + \gamma_{dt} + \theta_t \ln(\text{dist})_{od} + \varepsilon_{odt}$$

(a) β_t estimated annually

(b) β_t estimated every 5 years

Notes: Figure III plots the β_t point estimates and 95 percent confidence intervals for the specification given in equation 8 estimated on the country-level panel of trade. β_t is the treatment coefficient on the effect of exposure to failed banks on exports in each group of years. Point estimates and standard errors are scaled by the mean of treatment, so the magnitudes should be interpreted as the effect for the average exporter. The dependent variable is the log value of exports. The specification includes origin country o FE, destination country-year dt FE, and time-varying controls for the bilateral distance between countries. Standard errors are clustered by the origin country. See Table G12 column 1 for the point estimates.

on the estimated coefficients for trade costs. Appendix F provides the full derivation of the estimating equation.

The structural estimation requires a measure for origin-country size, which is typically proxied with GDP. Historical GDP data is not available for all countries, so the results are estimated on a smaller set of observations. In addition, since these data are less reliable than trade data, I do not impose the additional requirement that trade and GDP have unit elasticities throughout the sample. I plot the results from this estimation in Figure IV along with the reduced form, where I again scale the coefficients by the average exposure. The two-period unscaled post-crisis β_t estimated on this subsample is -1.50 (se 0.41) for the reduced form and -1.88 (se 0.84) for the structural approach. While the estimated effects from this approach is 25% larger in magnitude and even more persistent, it is not statistically different from the baseline.

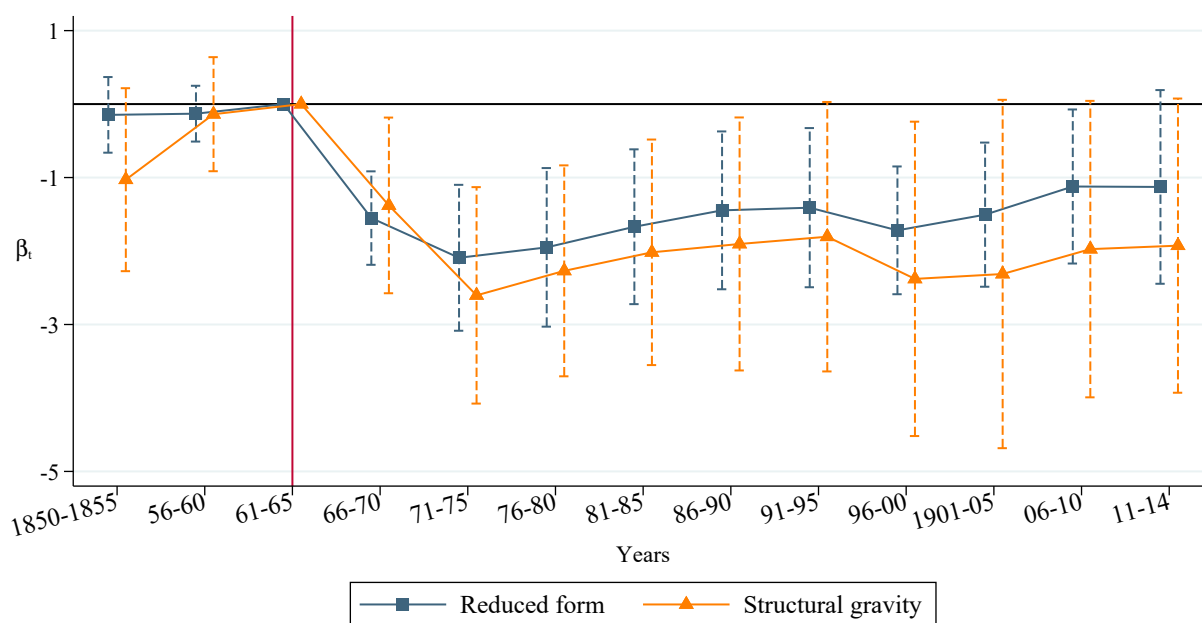

Table F1 reports the coefficients from adding GDP controls, the baseline estimated on the same sample of observations, and this structural approach. Restricting the baseline estimation to the subset of countries with GDP data partly accounts for the difference in magnitudes (column 1 versus 2), as does directly controlling for GDP (column 2 versus 3). Adding the Baier and Bergstrand (2009) multilateral resistance terms (column 4) leads to estimates that are completely persistent. Overall, the qualitative similarity in these results relative to the reduced form baseline indicates that unobserved bias arising from not directly controlling for changes in multilateral resistance is small. Given the stronger assumptions that the financing shock only impacted trade costs, and the empirical limitations of the smaller sample size and lower quality of GDP data, I present the structural approach as a secondary set of results and refer to the reduced form approach as the baseline.

No effect on imports

Exposure to bank failures does not impact a country’s imports, consistent with the institutional context that banks were not financing consumption. I estimate the impact of the crisis on a country’s imports using the baseline specification in Equation 8, replacing the key regressor of the exporting country’s exposure with the exposure to bank failure in the importing country.⁵⁴ As in the baseline, I saturate the estimation with fixed effects to account for exporter supply shocks (γ_{ot}) and the importer’s overall size (γ_d). I present these results in Table A9. Column 2 shows that exposure to bank failures has no impact on a

⁵⁴Given the symmetry in trade flows, one country’s exports is its trade partner’s imports. Therefore estimating the impact of country A’s exposure to bank failures on the amount it *imports* from country B is equivalent to estimating the effect of country B’s exposure to bank failures on the amount that exported to country A. The equation of interest, $\ln(IM_{dot}) = \beta_t \text{Fail}_o + \varepsilon_{odt}$, is equivalent to $\ln(EX_{odt}) = \beta_t \text{Fail}_d + \varepsilon_{odt}$. Note that in the notation IM_{dot} , the goods are traveling from country o to country d at time t .

FIGURE IV: Persistent effects: comparing baseline with structural version

Notes: Figure IV plots the point estimates and 95 percent confidence intervals for two separately estimated regressions. The one labeled “Reduced form” follows the specification in Equation 8 that estimates the reduced form β without controlling for multilateral resistance terms. The one labeled “Structural gravity” corresponds to the coefficients in Table F1 column 4 that estimates both the ϕ and ψ in the estimating equation F7. Standard errors are clustered by the origin country.

country's imports with coefficients close to zero and not statistically significant. In column 3, the import effects are robust to controlling for the shock to exporters as well.⁵⁵

Robustness

I provide several robustness checks for the long-run exports effects in Appendix G.2. First, I control for a wide variety of initial and contemporaneous macro-economic conditions that could be sources of omitted variable bias. In Table G12 columns 3–8, I show robustness to origin-country controls, including the pre-crisis characteristics that are correlated with bank failures. In Table G13, I report the estimates after including additional gravity covariates, such as shared language, shared land border, and being in the same European empire. I control for pre-crisis and contemporary military conflicts and exchange rate regimes (Table G14); industry composition of exports pre-crisis and initial trade intensity with the UK (Tables G15 – G17); exclude the cotton-exporting countries (Table G18); control for financial crises like sovereign debt, domestic debt, stock market crashes both contemporaneous and in 1865 (Table G19 and G20); account for the trade cost changes from the Suez Canal opening in 1869 (Table G21)⁵⁶; and exclude islands and entrepôts (Table G22). The static and the time-varying versions of all of these controls do not affect the statistical significance or the qualitative patterns of the results, and they make it unlikely that these other events were the actual drivers of the persistent collapse in exports market share.

Second, I generalize the concern that any individual country is affecting the results by estimating the baseline specification while dropping each exporting country in turn. In Figure G3, I plot the distribution of the estimated coefficients as well as the distribution of the associated p-values. These show that not only are the magnitudes of the coefficients robust, but also the patterns of statistical significance are as well. The coefficients before the shock are close to zero and not significant, and as in the baseline results, they become large in magnitude and economically significant after 1866 before exhibiting recovery in 1900. This robustness check also helps to address the potential concern that the results are driven by a small number of countries that experienced unobserved positive shocks after 1866.

Third, I implement the Fisher exact test for randomization inference. This test is conducted by reassigning treatment randomly and without replacement to countries to compare the estimated treatment effect against thousands of placebos. At longer time horizons,

⁵⁵Directly controlling for the importer's exposure to the crisis makes it impossible to include the full set of controls, such as the destination-year fixed effects that are included in the baseline estimations. Not being able to fully and flexibly control for demand shocks from importers attenuates the estimated effect of the crisis on exporters.

⁵⁶The Suez Canal primarily reduced trade costs between Asia/Oceania and Europe/east coast of the Americas. I allow for this differential change in bilateral trade costs using data collected by Pascali (2017).

countries' exports could be affected by a number of reasons, and assigning the treatment randomly will show whether the long-term negative effects could arise naturally from the data for reasons unrelated to the financing shock. If that is the case, the distribution of estimated coefficients will become more negative with each subsequent group of years. In this test, I redistribute the shocks randomly and simulate the data 1,000 times, and then I estimate the long-term effects in Equation 8 using the simulated data. I plot the distribution of the estimated coefficients for each β_t coefficient in Figure G4, which shows that the coefficients are centered around zero in all periods. The lack of drift indicates that the long-term effects are statistically very unlikely to have been generated by unobserved processes of divergence.

The large number of fixed effects and controls for observable characteristics, the balance on the correlation between the shock and pre-crisis characteristics, and the lack of differential pre-trends help to address many concerns about omitted variable bias. However, given the long time horizon of the estimated effects, it is impossible to rule out that other unobserved economic shocks or secular trends and developments may have contributed to the persistent effects that I find.

VI. CHANGES TO TRADE PATTERNS

VI.A *New sourcing by importers*

To better understand the cause of exporters' persistent market share losses, I examine how their trade partners (the importers) reacted to exporters being exposed to the shock. Guided by the conceptual framework, for each importer, I proxy for the financing shock's impact on the importer's own price index with its pre-crisis trade partners' exposure. Destinations reliant on more-exposed exporters were indirectly exposed to bank failures because the change in financing costs was either passed on in the form of higher prices or fewer varieties. The third prediction in the framework is that the higher price index from indirect exposure to bank failures will then make a destination more profitable and induce new exporters to enter.

I examine the impact of indirect exposure on a country's aggregate imports. I retain the notation from the baseline specifications with importers labeled as country d and exporters labeled as country o . I calculate indirect exposure denoted as $\overline{Fail}_{d,pre}$ by weighting a country d 's trade partners' exposure o using the three years of trade flows prior to 1866.⁵⁷

⁵⁷The results are virtually unchanged by using trade shares calculated with data from 1–5 years pre-crisis.

The specification for the impact of indirect exposure on total imports is:

$$\ln(IM_{dt}) = \beta_t \overline{Fail}_{d,pre} + \gamma_d + \gamma_t + \varepsilon_{dt} \quad (9)$$

I plot these results in Figure Va. First, I find that more indirectly exposed importers did not systematically buy less than other importers. Next, I estimate and decompose the effects on aggregate imports into the effect on the number of trade relationships and the average imports per relationship. These specifications follow the same form as Equation 9, with the different dependent variables as noted. Total imports were not significantly impacted, but indirect exposure led to more trade linkages after the shock with a concomitant decline in average imports per source.

While on average importers sourced less from each country, there is significant heterogeneity in the exporters that lost market share. A second decomposition of the aggregate imports into the share of total imports between new trade partners formed after the shock versus pre-existing trade partners shows that the pre-existing relationships with high exposure experience a sharp decline in total market share.⁵⁸ I plot these results in Figure Vb. This market share decomposition has the same overall pattern as the market share losses in the baseline estimation.

Comparing substitutable exporters

So far I have shown that a trade cost shock between parties leads importers to increase the share they buy from unexposed countries and to source from new relationships. In the 19th century, most countries exported commodities that were often produced in multiple locations, likely leading to a high degree of substitutability across countries. For example, a country importing sugar could choose among many producers in the Caribbean and South America. A large shock to the cost of exporting from one country can give its competitors a relative advantage in each destination where those competitors can enter and capture market share. Once importers establish a relationship, it may be difficult for exporters who had experienced a shock to regain their lost market share, even after the shock passes.

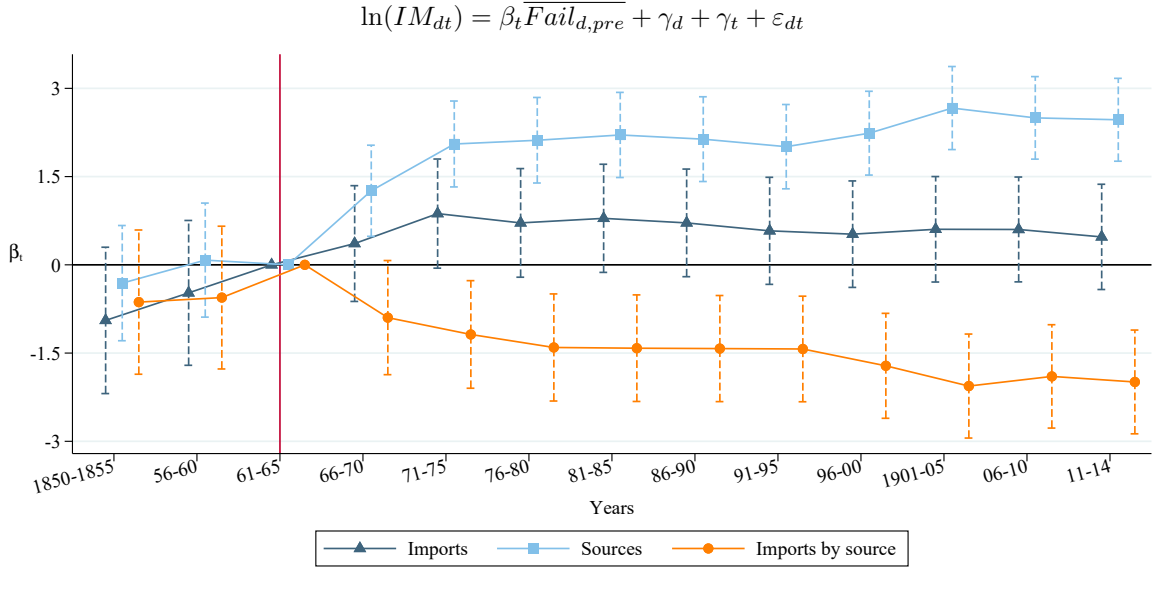

First, I use the industry composition of a country's total exports pre-crisis, categorized by two-digit SITC codes, to test for importers substituting among similar countries.⁵⁹

⁵⁸Note that in a world of growing levels of aggregate trade, the reduction in market share from this decomposition does not require that importers are buying less in absolute levels from pre-existing exporters relative to before the shock, but just that the denominator of total imports is growing faster than the numerator.

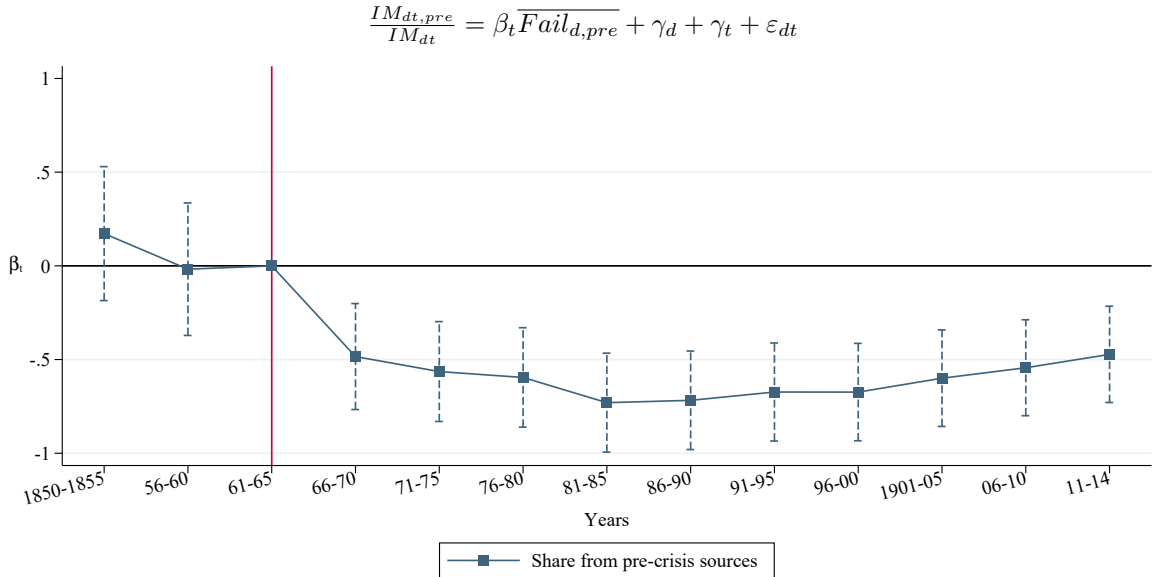

⁵⁹As noted in Section III, the industrial composition of exports at the bilateral level is not systematically available, and hence it is not possible to use industry-origin-destination variation.

FIGURE V: Decomposition of effect of indirect exposure on importers

(a) Decomposition of total imports, import sources, and average imports per source

(b) Decomposition of total market share

Notes: Figure Va plots the β_t point estimates and 95 percent confidence intervals for three separately estimated regressions of the specification written above and the dependent variable indicated. The specification includes destination (importer) d and year fixed effects. The dependent variable is the log of total imports (dark blue triangle), the log of number of trade partners (light blue square), and the log of average imports per source (orange circle). $\overline{Fail_{d,pre}} = \sum_o s_{od} Fail_o$ where $s_{od} = \frac{IM_{do}}{IM_d}$. The estimated effects are not scaled by average indirect exposure, so they should be interpreted as the effect if all of an importer's trade partners pre-crisis were fully exposed to the bank failures. Figure Vb has the share of total imports from pre-crisis trade partners as the dependent variable. Standard errors are clustered by destination country. The observations are weighted by country size proxied by number of trading partners in order to mostly closely mirror the aggregates in Figure II.

I estimate the baseline specification in Equation 8 with time-varying industry controls where each country is assigned the SITC industry of its biggest exports in 1865. The SITC industry controls mean that β_t should be interpreted as the loss of market share into a given destination in a given year by an exporting country *relative* to other countries whose exports also concentrated in the same industry. This estimation is restricted to the 44 countries that reported the composition of their exports in 1865, and they show that the direct comparison implies larger and more persistent losses (coefficients reported in Table G12 column 6 and plotted in Figure B10a).

Second, I broaden the measure of a country’s export composition by using its geographic region as a proxy. I validate that geographic region is a reasonable proxy for the goods exported for the subset of 44 countries with observable industry composition in 1865. For each region, I identify the top three export categories by SITC codes and calculate the fraction of the total value of exports from the region that fall into those categories.⁶⁰ This fraction is equivalent to an exports-weighted average of the cross-country export concentration within the top three categories. Figure B11 shows that this fraction is above 0.5 for all regions and averages 0.73 across regions, indicating that the industry composition of exports is very similar within region.

I compare the countries within regions to each other by including origin-country region-year fixed effects in the baseline specification in Equation 8. The additional controls restrict the variation such that β_t is estimated off comparisons of countries in the same geographic area exporting to the same destination in the same year. Figure VI (Table G12 column 8) shows that there is no recovery in this setting. As robustness, I also re-estimate the baseline with region-year fixed effects using the subsample of countries that have SITC information and verify that the patterns are similar (Table G12 column 7 and plotted in Figure B10b).

I also find evidence of this mechanism in the analogous estimation using the short-run port-level panel. I ask whether the average exposure of other ports within a country benefits a given port’s trade, both overall and to a specific destination. I calculate the average exposure to bank failures leaving out the port’s own city of financing.⁶¹ As in the country-level analysis, $\psi > 0$ indicates that a port benefits when it is in a country where the

⁶⁰Each region has at least two countries, and the primary exports for all countries outside of Northwest Europe are raw commodity goods.

⁶¹This measure is calculated by removing each city of financing’s contribution from the country-level exposure measure rather than simply leaving out the port’s exposure in order not to double-count cities that financed more than one port. The specification is: $\ln(S_{pot}) = \beta \text{Fail}_{po} \times \text{Post}_t + \psi \overline{\text{Fail}}_{other,o} \times \text{Post}_t + \alpha_p + \Gamma' X_{pot} + \varepsilon_{pot}$.

FIGURE VI: Persistent effects within groups of countries with similar exports

$$\ln(EX_{odt}) = \beta_t \text{Fail}_o + \Gamma' X_{ot} + \gamma_o + \gamma_{dt} + \psi \text{Region}_{ot} + \theta_t \ln(\text{dist})_{od} + \varepsilon_{odt}$$

Notes: Figure VI plots the point estimates and 95 percent confidence intervals for the specification given above estimated on the country-level panel of trade. β_t is the treatment coefficient on the effect of exposure to failed banks on exports in each group of years. Point estimates and standard errors are scaled by the mean of treatment, so the magnitudes should be interpreted as the effect for the average exporter. The dependent variable is the log value of exports. The specification includes origin-country region-year FE, origin country o FE, destination country-year dt FE, and time-varying controls for the bilateral distance between countries. Standard errors are clustered by the origin country. See Table G12 column 8 for the point estimates.

rest of the ports are more exposed. Appendix Table A5 columns 1–2 present the result for total exports from a port.

The sustained persistence of the effects within regions are not driven by the smaller sample comparisons. In a robustness check, I conduct an additional Fisher exact test for the regional assignments of countries by simulating 1,000 random group assignments and re-estimating the coefficients. I plot the distribution of the five-year coefficients in Figure G5. This figure shows that after 1900, the true coefficients are larger in magnitude than the average simulated coefficient, which implies that the true effects within regions are more persistence than random groupings would generate.

VI.B Heterogeneity

Lower financial needs

First, shorter routes are likely less expensive to finance because goods spend less time in transit, implying that trade between more distant partners will decline relatively more.

I test this prediction using the panel of country-level values of trade by allowing for the exposure to the financial shock to differentially affect trading partners that are physically closer. I construct a binary variable *Close* to indicate country-pairs that are less than the average distance between countries trading in 1865 and interact it with the origin-country exposure to the financial shock.⁶² Figure B12 plots the baseline effect of exposure β_t in orange and the additional effect of failure for close relationships $\theta_{t,close}$ in blue. β_t is very similar to the baseline effect in previous estimations. $\theta_{t,close} > 0$ indicates that conditional on exposure to bank failures, exports to closer destinations are positively affected. The main effect for exports to close destinations is given by $\theta_{t,close} + \beta_t$, which is close to zero. The qualitative interpretation is that a country’s export losses are borne by more distant trading partners.

Second, shorter institutional distance, as proxied by trade between two countries in the same colony, may also be less expensive to finance. I test this prediction in a similar way by constructing an indicator variable for country-pairs that are trading with their colony or colonizer. The baseline coefficients for *Failure* are plotted in orange and the additional heterogeneity in blue in Figure B13. These results show that exposed countries lost market share on average (the baseline negative effects in orange) but were able to compensate for some of those losses with colonial trade (the blue positive effects).

Access to alternative sources of financing

⁶²The specification is: $\ln(EX_{odt}) = \theta_{t,close}Fail_o \times \mathbb{1}(Close_{od}) + \beta_t Fail_o + \lambda_t \mathbb{1}(Close_{od}) + \Psi' X_{od} + \gamma_o + \gamma_{dt} + \varepsilon_{odt}$

Exporters that were not funded just by British banks would have been more likely to be able to draw on these lines of credit during the crisis, thereby shielding themselves from the higher marginal costs from British bank failures.

I use the port-level panel to test this hypothesis in the short-term using within-country variation. I do not observe non-British financing relationships directly so I proxy for them using the number of non-British banks pre-crisis. I re-estimate Equation 5 with an interaction term between exposure to failure and the number of non-British banks.⁶³ ϕ is the main coefficient of interest and captures the additional impact of failure on locations with non-British banks. Appendix table A5 (columns 3 and 4) shows that having access to more non-British banks pre-crisis mitigated the main losses ($\phi > 0$). The magnitude of ϕ is 53% of the baseline effect. The average port had access to 0.5 non-British banks, so assuming that non-British banks were as effective as British banks in providing trade financing, this access to other bank-intermediated finance mitigated the main effect by 26%.⁶⁴

Benchmarking the magnitudes

This paper shows that the effect of the financing shock on exposed exporters' aggregate export levels is permanent and that the market-share losses last for several decades. These persistent effects reflect changes in the shape of trade where exposed countries lost market share to unexposed countries. In a final exercise, I benchmark the total losses in exports against existing estimates at shorter horizons in the trade and macroeconomic literatures. While there is no comparable long-run study, the immediate and medium-run dynamics yield similar magnitudes.

The long-term effects of the shock on a country's total exports stems from two components: a large immediate difference in growth rates (consistent with the short-run intensive and extensive margin effects) and a lack of *additional* positive growth to compensate for the initial divergence in levels.

First, I benchmark the immediate growth rate difference against estimates of the elasticity of trade with respect to geographic distance and information frictions (see Anderson and Van Wincoop (2004) for a review of the importance of these and other frictions). The difference in post-crisis growth rates of aggregate exports after two years is 7.9% for unexposed countries relative to countries with average (9 pp) exposure. Using my dataset, I estimate a trade cost elasticity of -1.2 to geodesic distance.⁶⁵ Given this elasticity, the effect

⁶³The specification is: $\ln(S_{pot}) = \beta \text{Fail}_{po} \times \text{Post}_t + \phi \text{Fail}_{po} \times \text{non-Brit}_{po} \times \text{Post}_t + \alpha_p + \gamma_{ot} + \Gamma' X_{pot} + \varepsilon_{pot}$

⁶⁴Data on non-British banks are from Xu (2020).

⁶⁵This elasticity is, coincidentally, almost exactly the average elasticity found in the literature based on the survey of structural gravity by Head and Mayer (2014). Table A6 reports the estimates and robustness to controlling for gravity measurements of bilateral resistance.

on total exports from the average level of exposure is equivalent to increasing a country's geographic distance to its trading partners by 6.6%. Separately, the aggregate loss of 7.9% is similar in magnitude to Steinwender (2018)'s finding that connecting the Transatlantic telegraph resulted in an immediate efficiency gain equivalent to 8% of export values.

Second, there is no compensating growth even though annual growth rates reconverge almost completely within ten years, leaving a permanent effect on levels. These dynamics of lack of recovery in levels are consistent with the medium-term empirical evidence that crises lower the levels of output relative to a no-crisis counterfactual (Cerra and Saxena, 2008).⁶⁶

Note that the difference-in-differences partial equilibrium analysis in this paper cannot speak to the general equilibrium effects for aggregate global trade, and in particular does not provide a counterfactual for the total amount of world trade lost due to the crisis. The persistent relative market share losses also do not imply negative growth rates. Therefore simply adding the partial equilibrium losses across countries as is often done with more macro estimations, likely overstates the aggregate global impact.

VII. CONCLUSION

Despite the prevalence of financial shocks and the general consensus that they impact short-run outcomes, there is little causal evidence that these temporary events can have long-run effect on the patterns of economic activity. This paper uses a salient historical setting and novel archival data to provide such causal evidence that trade patterns can be disrupted for decades. The first modern global banking crisis serves as a laboratory where London's role as the global financial center means that bank failures in London were transmitted to cities and countries around the world. Exposure to bank failures caused large immediate declines in exporting activity on both the intensive and extensive margins within and across countries. Ultimately, countries exposed to larger degrees of bank failures experienced permanently lower aggregate exports and market share losses in their exports destinations that persisted for four decades.

These persistent effects can be understood within a framework where establishing trade relationships entails significant sunk costs. Exporters exposed to the financial shock during the cusp of a major expansion in globalization were disadvantaged relative to their competitors. The patterns of substitution across trade partners provides further evidence for the importance of being competitive in world markets during this critical juncture in history.

The slow post-crisis recovery among advanced economies in recent decades suggests

⁶⁶While there are instances of countries exhibiting higher growth after a shock to recover losses in levels (notably historically in the US), this pattern is the exception rather than the norm. Cerra et al. (2020) provides an in-depth review and synthesis of this long literature.

that the historical record continues to be relevant for understanding long-run slowdowns. While this paper has provided one set of magnitudes in the context of international trade, gaining a broader understanding of how major shocks impact economies at longer horizons in other contexts would be a fruitful avenue for future research.
