## ABSTRACT

### Tax Rates and Tax Evasion: Evidence from 'Missing Imports' in China\*

Tax evasion, by its very nature, is difficult to observe. In this Paper, we present a case study of tax evasion in China. The novel feature of our approach is that at a very disaggregated level of individual products, we can measure evasion relatively precisely, by comparing the values that China reports as imports from Hong Kong with what Hong Kong reports as exports to China. We can match up this 'evasion gap' with the tariff and VAT tax schedule at the product level. The result is striking: using the data in 1998, we find that on average, a 1% increase in the tax rate results in a 3% increase in evasion. The result is similar when a first-difference specification is used with data in 1997 and 1998. This relationship is non-linear: the evasion elasticity is larger at high tax levels. Furthermore, the evasion gap is negatively correlated with the tax rates on closely related products, suggesting that part of the evasion takes place by misreporting the type of imports, in addition to under-reporting the value of imports. This effect is even more pronounced when the evasion gap is measured using quantities rather than values.

## 1. Introduction

This paper studies the responsiveness of tax evasion to tax rates. Much of the work in the theory and empirics of taxation has taken tax collection as given and often costlessly executed. This simplification is unlikely to be realistic: even within the United States, where tax collection is considered to be relatively efficient, about 17 percent of income taxes are estimated as unpaid (Slemrod and Yitzhaki, 2000). One particularly important issue, from both theoretical and policymaking perspectives, is understanding the relationship between tax rates and tax evasion. A number of models have evolved to incorporate tax evasion, but these models fail to provide a clear prediction regarding the impact of tax rates on evasion. In the pioneering work of Allingham and Sandmo (1972), the relationship between tax rates and evasion is positive, but this depends on particular assumptions of risk aversion and the punishment for evasion. A broader review of the literature reports that, more generally, theoretical predictions of the effect of tax rates on evasion are highly sensitive to modeling assumptions (Slemrod and Yitzhaki, 2000).<sup>1</sup> Furthermore, even if we believe that increased tax rates will encourage greater evasion, there is still a need to assess the magnitude of this effect. Hence, empirically examining the effect of tax rates on evasion would be very useful from the perspectives of both theory and policy. This has proven to be a challenging task due to the difficulties in measuring evasion, which by definition is not directly observed.

A number of indirect approaches have been used to infer the behavior of tax evasion from measurable quantities such as currency demand or the discrepancies between national income and product accounts (e.g., Gutmann, 1977, Feige, 1979, Tanzi, 1980). These approaches have been criticized by Slemrod and Yitzhaki in their survey paper on the subject, since “[n]one of these approaches is likely to be reliable...as their accuracy depends either on unverifiable assumptions or on how well the demand for currency is estimated” (Slemrod and Yitzhaki, 2000). Furthermore, these approaches do not naturally generate an estimate of the responsiveness of evasion to tax rates.

---

<sup>1</sup> Some models even yield strong predictions that run counter to the conventional wisdom that higher tax rates increase evasion. For example, the model of Yitzhaki (1974) predicts that if the punishment for

As a more direct approach to examining tax evasion, researchers have used data from the U.S. Taxpayer Compliance Measurement Program (TCMP) conducted by the U.S. Internal Revenue Service. Based on intensive audits of a random sample of tax returns, the data set gives information on reported taxable income and what auditors later conclude to be true taxable income. Using these data, Clotfelter (1983) estimated that tax evasion is positively associated with tax rates, with the elasticity ranging from 0.5 to 3. Feinstein (1991), using a short panel of two years of TCMP data (1982 and 1985), found that increasing the marginal tax rate has a negative effect on evasion, contradicting Clotfelter's conclusion. However, the main source of variation on tax rates in both of these studies comes from differential marginal tax rates across income levels, so it is not really possible to disentangle tax rate effects from income effects.

In this paper, we take a new approach in measuring the effect of tax rates on evasion that is less likely to be contaminated by such problems. Specifically, we examine evasion in China's imports from Hong Kong, at a very disaggregated level (e.g., four-door passenger car), by comparing Hong Kong's reported exports and China's reported imports of the same products. In the absence of evasion (and measurement error), China and Hong Kong-reported numbers should be the same. So far, the extent to which they differ has generally been taken to be simple measurement error (see, for example, Feenstra and Hanson, 2000). However, when we match these data up with product-specific tax rates in China (tariff plus value-added tax rates), we find that this 'evasion gap' is highly correlated with Chinese tax rates: much more value is 'lost' for products with higher tax rates. Our methodology is related to that of Pritchett and Sethi (1994), who find that tax revenues divided by imports increase at a rate less than the official tax rate, in a sample of four developing countries. Note, however, that our analysis is at a much higher level of disaggregation; furthermore, they are unable to disentangle illegal tax *evasion* from legal tax *avoidance* (e.g., taking advantage of tax loopholes and special exemption). Tax avoidance, as it is legal, is more readily observed than evasion.<sup>2</sup>

---

evasion is dependent on the value of taxes evaded (as is the case in China), tax rate increases will reduce evasion.

<sup>2</sup> We note, finally, that there is a considerable literature on efforts by multinationals to reduce tax payments through methods such as transfer pricing and the allocation of profits across countries according to their tax rates (see, for example, Clausing, 1998; Bernard and Weiner, 1990). Once again, however, this literature examines tax avoidance rather than tax evasion.

Another novel feature of our study is that we are able to differentiate three different aspects of tax evasion: under-reporting of unit value, under-reporting of taxable quantities, and the mislabeling of higher-taxed products as lower-taxed products. We find strong evidence of mislabeling and limited evidence of under-reporting of unit value; on the other hand, once shifting reported imports from a higher- to a lower-taxed category is controlled for, we do not find evidence of under-reporting of overall imported quantities.<sup>3</sup> In looking at the effects of changes in tax rates between 1997 and 1998 on changes in evasion, we obtain similar results. Finally, when we use a flexible functional form, we find that tax evasion occurs mostly at higher tax rates. The rest of the paper is organized as follows: Section 2 describes the data on taxes and imports/exports. Section 3 provides the details of our empirical specification and the results. Finally, Section 4 concludes.

## 2. Data

The trade flow data in this paper are taken from the World Bank's World Integrated Trade Solution (WITS) database, which in turn is derived from the United Nations' Comtrade database. These data are collected by the United Nations Statistical Division from individual countries' trade records, and include information on imports and exports for each country, recorded according to the 6-digit Harmonized Commodity Description and Coding System (HS). The United Nations allows individual countries to have a classification system more detailed than the HS 6 digit levels. In the case of China, an 8-digit classification (a refined version of the HS 6-digit classification) is available. However, we choose to use the import data at the 6-digit level in order to be compatible with Hong Kong-reported numbers. The current HS classification system began in 1996, which is also the earliest year for which we have year-end data on tax rates.

For every product that China imports from Hong Kong, we define *Export\_Value* as the value of exports reported by Hong Kong destined for China and *Import\_Value* as

---

<sup>3</sup> Of course, outright smuggling that evades both Hong Kong and China's customs is not captured in our data set.

the value of imports reported by China arriving from Hong Kong. The original sample contained 5113 products at the 6-digit classification level in 1998. However, there were missing observations for 2820 classifications for either imports or exports.<sup>4</sup> Of those remaining, a further 250 did not have consistent tax rates at the 6-digit level, and were also omitted, leaving a final sample of 2043. Some regressions involve fewer observations due to missing observations on other regressors (details provided in Section 3).

Because of Hong Kong's proximity to China and its special status as a former colony, it also does a considerable amount of indirect trade on behalf of other economies (including Taiwan).<sup>5</sup> Hong Kong reports (in the Comtrade database) separate data on indirect as well as direct exports destined for China. China, on the other hand, only reports what it considers to be direct imports from Hong Kong. Indirect imports (say from the U.S. via Hong Kong) are aggregated, in principle, with direct imports from the source country and are reported as part of the imports from that source country. Thus, in theory, China-reported imports from Hong Kong should match up to Hong Kong-reported direct exports to China. However, the data suggests that China cannot always successfully separate indirect imports from direct imports. One likely source of confusion is Taiwan's indirect exports to China via Hong Kong. As the government of Taiwan does not allow its firms to have direct trade with China, Taiwan's exports to China often label Hong Kong as the destination. Sometimes shipping labels are modified while the goods are en route to Hong Kong or in a warehouse in Hong Kong. At other times, an intermediary in Hong Kong is used to record the transaction as an import by Hong Kong from Taiwan plus an export from Hong Kong to China. While the Hong

---

<sup>4</sup> These were almost exclusively missing observations on both imports and exports; where observations were available for imports and not for exports, it is almost certainly the result of misclassified re-exports (see below). When all regressions were repeated, using all observations on exports and redefining  $Gap\_Value = \log(1+Export\_Value) - \log(1+Import\_Value)$ , the sample size increased by about 2 percent, and our results were virtually identical to those reported in Section 3 below.

<sup>5</sup> Hong Kong's reliance on re-export trade has created the false impression that manufacturing activity is virtually nonexistent in Hong Kong itself. To counter this misconception, we refer to a recent study by the Chinese commercial law firm Johnson, Stokes, and Master (JSM), which described Hong Kong's manufactured exports as including, "a wide range of products including clothing, electronics, watches & clocks, jewelry, textiles and chemicals." Their complete report on Hong Kong may be downloaded from: <http://www.hg.org/guide-hongkong.html>. Note that if we limit our sample to the industry categories implied by JSM, the implied effect of the tax rate on evasion increases somewhat, and the fit of the regressions improves marginally.

Kong customs authorities may understand this as an indirect export to China, China might misclassify at least a portion of such transactions as being direct imports from Hong Kong.<sup>6</sup> It is important to note that, as the tariff and VAT rates are the same for a given product whether it is a direct or indirect import from Hong Kong, there is no tax advantage to mis-reporting between direct and indirect imports. We will return to this issue later.

Comtrade contains data on both the value and quantity of imports/exports; we will utilize both sets of data. In the case of quantities, we are also required to know the units of measurement (e.g., weight, number; area); in most cases, these values match up between the Chinese (import) and Hong Kong (export) data. Where they do not, it is primarily because China reports the weight of imports, while Hong Kong reports the number of units. These observations are not included in the quantity regressions. We define *Export\_Qty* to be the total quantity of exports from Hong Kong destined for China as reported by Hong Kong and *Import\_Qty* to be the total quantity of imports reported by Chinese customs from Hong Kong into China.

Our basic definition of the evasion gap is given by:

$$Gap\_Value = \log(Export\_Value) - \log(Import\_Value)$$

Thus defined, a larger gap is an indication of greater evasion. We similarly define the gap in quantities reported as:

$$Gap\_Qty = \log(Export\_Qty) - \log(Import\_Qty)$$

The data on Chinese tariffs and taxes were also taken from WITS, derived from the UNCTAD TRAINS (Trade Analysis and Information System) database, which gives tariff rates at the 8-digit HS level. Since our import/export data are at the 6-digit level, we need some way of aggregating up the tariff rates to the 6-digit level. Fortunately, there is relatively little variation in tax rates at the 6-digit level, so we are able to restrict

---

ourselves to the sample for which there are uniform rates at this level of aggregation.<sup>7</sup> In addition to tariffs, there is a value-added tax levied on most imports, which varies from 13 to 17 percent. Our measure of taxation,  $Tax_{1998}$ , is the sum of tariff and VAT tax.<sup>8</sup>

The earliest year for which we have data on tariffs is 1996, and our data reflect year-end tariff rates. Unfortunately, due to constantly shifting tariff rates in China throughout the years 1992-97, the appropriate tax rate to be utilized is unclear for this period (Lardy, 2000). In our benchmark regressions, we therefore report results utilizing data from 1998, the most recent year for which data were available on both imports and exports. As an extension, we also implement regressions using two years of data (1997 and 1998). We will explain the construction of the 1997 tax rate later in the paper.

Part of evasion may take place by mislabeling imported products from a higher-taxed to a lower-taxed type. It is reasonable to assume that this type of mis-labeling is easier for “similar” products. Operationally, two products are considered “similar” if they are in the same 4-digit category. We define  $Avg(Tax_o)$  to be the average level of  $Tax$  for all other products in a good’s 4-digit class, weighted by  $Export\_Value$ . For a full list of variables, definitions, and sources, see the Appendix.

Summary statistics for our variables are contained in Table 1A. One point to note is that the so-called evasion gap actually has a negative mean. This appears to be due to Chinese customs misattributing some portion of indirect imports as direct imports. In fact, when we exclude observations for which the ratio of direct to indirect exports (based on Hong Kong’s reporting) is very low, the evasion gap quickly rises above zero (see Table 1B). We will further discuss the complications that this may create later. Also note

<sup>6</sup> We thank Professor SUNG Yung-Wing at the Chinese University in Hong Kong for a helpful discussion on this issue.

<sup>7</sup> We may also utilize the full sample, by using the simple mean or median tariff rate for each 6-digit industry. However, since we do not know the composition of imports, this may add considerable noise to our tariff rate measurement. When we include products for which there is tariff variation at the 6-digit level, all results are weakened slightly (generally by a few percent), consistent with our measurement error interpretation.

<sup>8</sup> We argue that the sum of tariffs and the VAT is the most appropriate measure: if an importer already under-reports the value of a particular product, she would also evade the associated VAT. If a car is smuggled into the country without paying the tariff, it is reasonably likely to be sold on the black market without paying the VAT. However, as a robustness check, we have also replicated the key regressions when we restrict the tax variable to include only the tariff rate at the customs, but not the VAT. The results are virtually identical to those reported in the main text.

that the evasion gap is higher when measured in values rather than quantities; this is suggestive that some evasion takes the form of under-reporting of per unit values.

### 3. Empirical Analysis

#### Benchmark specification

We begin by defining the following:  $Export_k$  = Hong Kong reported direct exports of good  $k$  to China (which we take as the true import of good  $k$  by China from Hong Kong).  $Import_k$  = Direct imports of good  $k$  by China from Hong Kong as reported to Chinese Customs.

The prediction that we will be examining in the empirical test is that the difference between reported exports and imports is increasing in the tax rate, due to evasion. That is:

$$(1) \log(Export_k) - \log(Import_k) = \alpha + \beta Tax_k + \varepsilon_k$$

Tax-induced evasion implies that  $\beta > 0$ . Unfortunately, because China cannot always accurately separate indirect imports (e.g., U.S. exports to China passing through Hong Kong) from genuine direct imports from Hong Kong, we do not observe  $Import_k$  directly.<sup>9</sup> Instead, China's recorded imports from Hong Kong,  $Import^*_k$ , contains part of indirect imports misclassified as direct imports. In other words, we actually observe the following:

$$(2) Import^*_k = Import_k + Misclassified\ Indirect\ Import_k .$$

It is crucial to note that the same tax rate is applicable to both direct and indirect imports. Therefore, the magnitude of the misclassified indirect imports for a particular

---

<sup>9</sup> There are two types of indirect exports passing through Hong Kong to China. The first one, "transshipments," goes straight from ships docked at Hong Kong to trucks destined for China. The second involves a stopover in Hong Kong before being sent to China. The latter is likely where China gets confused about the true exporter.

product should be uncorrelated with the tax rate for that product (since there is no tax advantage from misclassification). Rather, it is plausibly proportional to the magnitude of the import of that product (subject to some random error). We will assume that

$$(3) \quad \text{Misclassified Indirect Import}_k = \theta \eta_k \text{ Import}_k$$

Where  $\theta$  is a constant, and  $\eta_k$  is an independent and identical random variable, with distributional assumptions to be made later. Thus,

$$(4) \quad \begin{aligned} \text{Import}^*_k &= \text{Import}_k + \text{Misclassified Indirect Import}_k \\ &= (1 + \theta \eta_k) \text{ Import}_k \end{aligned}$$

Combining these four equations, we obtain

$$(5) \quad \log(\text{Export}_k) - \log(\text{Import}^*_k) = \alpha^* + \beta \text{ Tax}_k + e_k$$

or equivalently:

$$\text{Gap\_Value}_k = \alpha^* + \beta \text{ Tax}_k + e_k$$

where  $\alpha^*$  is a (new) constant, and  $e_k$  a composite error term that is assumed to be iid and normal with a mean of zero and a constant variance. To be more precise, if we denote the mean of  $\varepsilon_k - \log(1 + \theta \eta_k)$  by  $\alpha_0$ , then,

$$(6) \quad \alpha^* \equiv \alpha - \alpha_0$$

and

$$(7) \quad e_k \equiv \varepsilon_k - \log(1 + \theta \eta_k) - \alpha_0 \sim \text{Normal}(0, \sigma_e^2)$$

Equation (5) will be the benchmark for our regression specifications. The results are reported in Table 2. In the first column, we have the basic estimate of the sensitivity of evasion to tax rates, which is 2.82. That is, if the tax rate increases by one percentage point, the gap between reported exports and imports increases by about three percent. When observations with the highest and lowest one percent of values of *Gap\_Value* are excluded, the coefficient is virtually unchanged, as seen in the second column. In order to make direct comparisons with other results reported in this paper, we also repeated this basic specification, using the sample of industries with observations on  $Avg(Tax_o)$ , and also limiting the sample to industries with observations on quantities. Changing the sample in this way has very little impact on the reported coefficient.

Unfortunately, because of the noise introduced by misclassified indirect imports, the fit of the regressions might be considered fairly poor. A common method of dealing with noisy data is aggregation. We follow this approach, using as the outcome variable the mean value of *Gap\_Value* for each tax rate. There are 44 different tax rates, thereby yielding a total of 44 observations. The basic relationship between the mean value of *Gap\_Value* and tax rates is illustrated in Figure 1, and is suggestive of a positive correlation. Results for the regression weighted by number of observations per tax rate, as well as the unweighted regression, are listed in Table 3, columns 1 and 2. The coefficient on *Tax*, 3.10, is similar to the baseline regressions from Table 2, and is significant at the one percent level. Moreover, the  $R^2$  increases to 0.26. The unweighted regression yields virtually identical results. Taking means is a linear operation, which allows for the same interpretation of these coefficients as in Table 2. As an alternative way to reduce the noise in the data, we also use the median of *Gap\_Value*, for each tax rate, as the outcome variable. This approach has the advantage of further limiting the effect of outliers in the data (though the interpretation of the coefficient on *Tax* is not as straightforward); the results, reported in columns 3 and 4 of Table 3, are the same as those obtained from the mean regressions. Again, the point estimate on the tax rate is approximately 3, and the goodness-of-fit as measured by the adjusted R-squared has increased to 0.3.

So far, we have concentrated our discussion on the statistical properties of the estimation. It may be useful at this point to also consider the economic implications of

the point estimation in terms of revenue collection. From (1), we can infer how reported imports may be affected by an increase in the tax rate:

$$(8) \quad \frac{(dImports/dTax)}{Imports} = \frac{(dExports/dTax)}{Exports} - \beta$$

So, the effect of a tax increase may reduce reported imports through two channels: by reducing the true imports (i.e., Hong Kong's exports, the first term in (8)); and by reducing the fraction of true imports that is reported to Chinese Customs ( $-\beta$ , the second term in equation (8)). While we do not have a direct estimate of the first term in Equation (8), it is reasonable to assume that it is negative. Therefore, an estimate of  $\beta$  equal to 3 percent implies that, for any product whose tax rate exceeds 33.3 percent, a one-percentage point increase in the tax rate would lead to a more than one-percentage point reduction in reported imports. The average tax rate on imports (tariff plus VAT) in China is 36.1 percent (see Table 1). Therefore, one may infer that the average tax rate is already on the wrong side of the Laffer curve: at the average rate, any increase in the tax rate would actually produce a reduction in tax revenue.

### **Evasion by mis-labeling**

In addition to underreporting of the value of imports, evasion can also take the form of mis-labeling -- a higher-taxed good is reported as a lower-taxed variety. To investigate the existence of this type of evasion, we add the average tax rate of similar goods as a regressor. For a particular good  $k$ , its "similar products" are defined as all other products in the same 4-digit category.<sup>10</sup> Define  $Avg(Tax_o)$  to be the average tax rate for product  $k$ 's similar products, weighted by the value of their Hong Kong-reported exports. We implement a regression of the following form:

$$(9) \quad Gap\_Value_k = \alpha + \beta_1 * Tax_k + \beta_2 * Avg(Tax_o_k) + v_k$$

---

<sup>10</sup> We cannot look at the 5-digit level, because we have only a single observation in each 5-digit class for about 75 percent of the sample. We obtain very similar results to those reported in the main text if aggregation is at the 3-digit level.

If there is a significant component of mis-labeling of goods, we expect  $\beta_2 < 0$ . In other words, holding a product's own tax rate constant, the lower the tax rate on product  $k$ 's similar varieties, the greater the incentive to mis-report the import of  $k$  as other similar products.

Table 4 reports results with  $Avg(Tax_o)$  included as a regressor. Consistent with the mis-labeling interpretation, we find that the coefficient on  $Avg(Tax_o)$  is negative and significant at the 5 percent level, taking on values between -2.3 and -4.6. Furthermore, the inclusion of the average tax rate of similar goods as a regressor results in a substantial increase in the coefficient on  $Tax$ , which takes on values of 4.9 to 7.7.

We have also run regressions that replace the average tax rate with the minimum tax rate among all "similar" products. A possible rationale is that the tax-evader may want to mis-label the import as the lowest-taxed "similar" product rather than any "similar" product. However, using the minimum has a number of shortcomings: if only a relatively small volume of the minimum-tax product is reported leaving Hong Kong, it may be difficult to mis-label a large volume of imports as this product type. Furthermore, it may not be the product in the 4-digit class that most readily lends itself to mislabeling. In any case, empirically, this change in regressor has a very small impact on the estimated coefficients (results not reported to save space). When both the minimum and average tariff rates are included in the regressions, the coefficient on the minimum tariff rate loses its significance, while the coefficient on average tariff rates is relatively unaffected (results not reported to save space).

### **Quantity versus unit value**

So far, we have not separated the under-reporting of unit values versus the under-reporting of quantities; both will show up as a positive coefficient on  $Tax$  in the value regressions. We now turn to regressions that use the gap in imported quantity as the dependent variable. Specifically, we examine the following regressions:

$$(10) \quad Gap\_Qty_k = \alpha + \beta_1 * Tax_k + v_k$$

$$(11) \quad Gap\_Qty_k = \alpha + \beta_1 * Tax_k + \beta_2 * Avg(Tax_{o_k}) + v_k$$

If the under-reporting of quantities is prevalent, we expect to find a positive coefficient on  $Tax_k$  in the quantity regression (10),  $\beta_1 > 0$ . If there is mis-labeling of imports from a higher-taxed category to a lower-taxed one, we expect to find  $\beta_1 > 0$  and  $\beta_2 < 0$ .

Results parallel to those of Table 2 and 4, using  $Gap\_Qty$  as the dependent variable, are listed in Table 5. Interestingly, when  $Avg(Tax_o)$  is excluded from the regression, the coefficient on  $Tax$  is insignificantly different from zero. However, when  $Avg(Tax_o)$  is included, we find that the coefficient on  $Tax$  becomes significant, positive, and approximately equal to the coefficient on  $Avg(Tax_o)$  in absolute value. Thus, the data suggest that under-reporting of the total value of imports and mis-labeling the type of goods are prevalent, while under-reporting of the total quantities imported across all tax brackets is not significant.

### **Tariff exemptions**

Many of Hong Kong's imports into China are exempt from import tariffs. These exemptions presumably impact incentives for evasion, and could potentially be correlated with tariff rates, since high tax rates may increase incentives for exemption seeking.<sup>11</sup> More precisely, for products where exemptions are common, evasion may be less sensitive to tax rates than for products where exemptions are rare, since exemptions provide a legal means of avoiding tax payments.

We now describe how the fraction of imports that is exempt from taxation is calculated for each of the 6-digit products. First, we obtained data at the 8-digit level on the exemption status of imports from the *Chinese Customs Statistics 1998*. These data also include the value of China-reported imports from Hong Kong at the 8-digit level, which were used to calculate a weighted average of the proportion of imports exempt from tariffs for each 6-digit product, i.e.,

---

<sup>11</sup> In fact, there is a very low correlation between *Tax* and *Exemption*.

$$Exemption_{HS6} = \frac{\sum_{HS8 \in HS6} Import\_Value_{HS8} * Exempt_{HS8}}{\sum_{HS8 \in HS6} Import\_Value_{HS8}}$$

where *Exempt* is an indicator variable denoting whether a product is exempt from import tariffs, *HS6* denotes products at the 6-digit level of aggregation, and *HS8* denotes products at the 8-digit level of aggregation. Aggregating in this way is necessary in order to match to the Hong Kong-reported export data.

Table 6 shows the results of the following regression:

$$(12) \quad Gap\_Value_k = \alpha + \beta_1 * Tax_k + \beta_2 * Exemption_k + \beta_3 * Tax_k * Exemption_k \\ + \beta_4 * Avg(Tax\_o_k) + \beta_5 * Avg(Tax\_o_k) * Exemption_k + v_k$$

Consistent with higher exemption rates lowering the incentives for evasion, the coefficient on *Exemption* is consistently negative and significant (See columns (1) to (4)). When interacted with *Tax*, the coefficient is negative, highly significant, and approximately the same size as the coefficient on *Tax*. This implies that for a product with complete exemption in 1998 (i.e., *Exemption*=1), there is no effect on evasion from tax increases. By contrast, for industries with no exemptions, the implied elasticity is about 26 percent.<sup>12</sup> In looking at the effect of exemptions on incentives to re-label goods, we find that the coefficient on *Avg(Tax\_o)\*Exemption* is positive, though not significant at conventional levels (t-statistic of 1.4), implying less re-labeling for goods with high exemption levels. In columns (5) to (8), we report the results of the same regressions, using *Gap\_Qty* as the outcome variable, and obtain qualitatively very similar results.

---

<sup>12</sup> This figure seems unreasonably large; if we omit outliers of *Gap\_Value*, the implied elasticity of evasion with respect to taxes drops to 16 percent, while the significance of all coefficients in this regression are more or less unchanged. Also, there may be concerns that, because most of the exemption ratios are relatively high (the 25<sup>th</sup> percentile of *Exemption* is 0.68), making inferences about the effects of evasion at *Exemption* = 0 is too far out of sample. However, when we run regressions comparable to those reported in Table 6, limiting the sample to observations with *Exemption* < 0.5, we obtain a coefficient on *Tax* of 22. This suggests that functional form is *not* driving our results on the interaction of *Tax* and *Exemption*.

### First differences in tax rates

Our primary results suggest a strong effect of taxes on evasion, acting through both under-pricing and product mis-labeling to lower-taxed categories. There may be concerns, however, that certain features of different products that are not directly measured and not included in the regressions may be driving the results. While we do not have specific factors in mind that may bias our result, to be on the safe side, we now use two years of data and adopt a first-difference specification that can net out time-invariant and product-specific determinants of tax evasion. More precisely, we estimate the following:

$$(12) \quad DGap\_Value_k = \alpha + \beta_1 * DTax_k + \beta_2 * DAvG(Tax_{ok}) + v_k$$

where a prefix *D-* denotes the change between 1997 and 1998.

Determining the appropriate tax rate for 1997 turns out to be a little challenging. While there was virtually no change in the tariff structure during 1998, there was a fairly large-scale tariff reform on October 1, 1997.<sup>13</sup> Since our import data for 1997 was cumulated for the year, we have to use the weighted average of tax rates that prevailed before and after the tariff reform. However, the knowledge of a tariff reform in the near future could affect the timing of the imports. We do not have a good way to correct for this. Instead, we assume that the effective tax rate for 1997 is given by:

$$Tax_{1997} = 0.75 * (\text{Year-end tax rate for 1996}) + 0.25 * (\text{Year-end tax rate for 1997})$$

We then define  $DTax = Tax_{1998} - Tax_{1997}$ .

Table 7 shows the estimation results. We note that the R-squared values are very low in these regressions; this is not surprising, as we have differenced out much of the information in the data. In columns (1) and (2), with the change in *Gap\_Value* as the dependent variable, the coefficient on *DTax* is significant, though marginally smaller than

---

<sup>13</sup> There was also a large-scale tax reform on April 1, 1996. Since we do not have tariff rates for year-end 1995, it is not possible to calculate average tax rates for 1996. We simply assume the average tax rate to be the year-end rate, and run a fixed-effects regression with three years of data. In this case, we obtain results that imply a slightly larger rate of evasion than that reported in the main text.

that obtained in our level regressions. The coefficient on  $Davg(Tax_o)$  is no longer significant at conventional levels (t-statistic of approximately one), but is of the same sign as in the level regressions. We obtain similar results with the change in  $Gap_Qty$  as the dependent variable (see columns (3) and (4)).

### **Flexible functional form**

We now allow the marginal effect of a tax increase on evasion to differ across different tax rates. Following, for example, Chamberlain (1997), we allow for the slope to differ across quartiles, with knots at tax rates of 29, 34, and 42 percent. The results, in Table 8, suggest that there is little effect on evasion at relatively low tax rates. However, as tax rates rise above the median level of 34 percent, the extent of evasion rises dramatically. The marginal effect then tapers off again at higher levels. As before, the effect of tax rate increases is larger when we control for average tax levels by 4-digit HS.

This pattern of non-linearity is consistent with the existence of a fixed cost in undertaking evasion activity. For example, if there is some fixity in the punishment for evasion, there may be a threshold tax level above which evasion becomes worthwhile.<sup>14</sup> Alternatively, it is also consistent with a probability of detection that is relatively invariant to the tax rate, so that the benefit of evasion increases more rapidly than the cost as tax rates increase.

### **Robustness to Alternative Specifications of Indirect exports**

As noted in the data section of this paper, the Chinese customs-reported import figures are likely to include part of the indirect imports that are mis-classified as direct imports. We have argued that the amount of such mis-classified imports should not be correlated with the tax rate on the product since the same tax rate is applied to both direct and indirect imports. We can make a more direct assessment of this assumption by restricting our sample to those products for which Hong Kong sends relatively few indirect exports to China.

---

<sup>14</sup> Unfortunately, the punishment code for customs evasion in China is sufficiently vague as to give relatively little guidance on this question. While the punishment includes the confiscation of the goods involved, it also may incorporate a fine of an unspecified amount. Furthermore, in recent years, some

We repeated the basic regressions from Tables 2 and 3, excluding observations with relatively low values of  $Direct\ Export\ Ratio = (Direct\ Export)/(Indirect\ Export + Direct\ Export)$ . We use cut-off values of 0.01, 0.05, and 0.1; the results using export values are reported in Table 9. In the case of the simple binary regression, the coefficient on  $Tax$  increases slightly with the cut-off. The qualitative inference, however, remains the same. The results with  $Avg(Tax_o)$  included as a regressor are somewhat mixed, possibly owing to the colinearity of  $Tax$  and  $Avg(Tax_o)$  once the sample size has been reduced. When we look at the results from the quantity regressions, the coefficients are uniformly suggestive of a stronger effect of tax rates on evasion, when products with relatively low ratios of direct exports are excluded (See Table 10).<sup>15</sup>

#### 4. Conclusions

In this paper, we take a new approach in measuring the effect of tax rates on tax evasion, by looking at the reporting gap in China's imports from Hong Kong, as a function of Chinese tax rates (tariff plus VAT rates). We find that this 'evasion gap' is highly correlated with tax rates: much more value is 'lost' for products with higher tax rates. The point estimates suggest that the Chinese average tax rate on its imports is already on the wrong side of the Laffer curve: any increase in tax rate is likely to produce a reduction rather than an increase in tax revenue.

By comparing the evasion gap in quantities and in values, we conclude that there are widespread practices of under-reporting the unit values of imports, and mis-labeling higher-taxed products as lower-taxed varieties.

As a broader contribution to the literature, we believe that our approach can be applied to other countries as well. In addition to providing more information on the behavioral response of tax evasion to tax rates, the generalized multiple-country study could provide a more objective measure of the laxity of rule of law across countries – in

---

traders have been executed for tariff evasion, thereby highlighting the full extent of autonomy that the authorities have in determining punishments.

<sup>15</sup> An alternative approach, since we are estimating a very reduced form of the evasion equation, is to simply include the value of indirect exports as a regressor. The results from this approach are virtually identical to those previously reported.

contrast to the subjective perception based measures of corruption and rule of law now popular in empirical studies. We leave this, and other extensions, for future work.

## Appendix: Variable Definitions

**Import\_Value:** Value of imports from Hong Kong into China, as reported by the Chinese customs, for 1998, at the 6-digit HS level. Measured in U.S. dollars. Source: World Bank's World Integrated Trade Solutions (WITS), derived from the United Nations' Comtrade Database.

**Export\_Value:** Value of exports by Hong Kong destined for China, as reported by Hong Kong customs, for 1998, at the 6-digit HS level. Measured in U.S. dollars. Source: WITS

**Indirect Export\_Value:** Value of Indirect Exports from Hong Kong to China, originating from third-party countries. Reported by the Hong Kong customs, for 1998, at the 6-digit HS level. Measured in U.S. dollars. Source: WITS

$$\mathit{Gap\_Value} = \log(\mathit{Import\_Value}) - \log(\mathit{Export\_Value})$$

**Import\_Qty:** Quantity of imports from Hong Kong into China, as reported by the Chinese customs, for 1998, at the 6-digit HS level. Measured in U.S. dollars. Source: WITS

**Export\_Qty:** Quantity of exports from Hong Kong destined for China, as reported by Hong Kong customs, for 1998, at the 6-digit HS level. Measured in U.S. dollars. Source: WITS

**Indirect Export\_Quantity:** Quantity of indirect exports, originating from third-party countries. Reported by the Hong Kong customs, for 1998, at the 6-digit HS level. Measured in U.S. dollars. Source: WITS

$$\mathit{Gap\_Qty} = \log(\mathit{Import\_Qty}) - \log(\mathit{Export\_Qty})$$

**Tax:** Total taxes rate levied on incoming goods by the Chinese Authorities, equal to the sum of tariffs and commercial taxes, for 1998. Source: WITS

**Dtax:** Difference in the tax rates in 1998 and 1997. See the text for details.

**Exemption:** At the 6-digit level, the proportion of goods exempt from import tariffs. Source: China Customs Statistics, purchased from the EIA CCS Information Service Center in Hong Kong.

**Avg(Tax\_o):** Average of the level of *Tax* for all other goods in a product's 4-digit HS class, weighted by *Export\_Value*.

**Direct Export Ratio:** Ratio of Direct Exports to Direct Exports + Indirect Exports
