## **ABSTRACT**

### Learning to be an Entrepreneur\*

Is entrepreneurial talent entirely innate or do people learn to become entrepreneurs? We extend Lucas's (1978) model of entrepreneurship to allow for the possibility that entrepreneurial talents may be acquired by watching other entrepreneurs in action. This model implies that areas with a greater number of firms have higher average firm productivity. We confirm this prediction using Italian firm level data. We show that the endogenous accumulation of entrepreneurial talents is a more convincing explanation for clusters of firms than heterogeneous entry costs. The evidence supports the role of learning even after controlling for other potential sources of local externalities. We also find that other specific implications of the learning mechanism are confirmed by the data.

# 1 Introduction

There is a vast literature linking a country's endowment of "entrepreneurship" with economic prosperity. Nations with an environment where entrepreneurs can emerge easily are propitious to the creation of firms, their growth and their success. These ideas date back to Marshall (1890) and to Schumpeter (1911), who sees the entrepreneur as the carrier of innovation and hence the true engine of economic growth. But if entrepreneurship is so central to economic development, what drives it? Why are there so many entrepreneurs in some areas, such as Silicon Valley, and so few in others? Do these differences just reflect differences in opportunities driven by - say - the presence of Stanford University? Why don't we observe the same explosion of entrepreneurs in Massachusetts? Why do we find these clusters in some countries rather than others, and in particular areas within countries, such as in the Italian industrial districts or the Ruhr? These important questions have often been in the forefront of policy debate and government intervention.

The literature has focused on the factors - particularly financial - that keep the would-be entrepreneur from actually creating a new firm. Banerjee and Newman (1994), for instance, show that credit constraints can lead to poverty traps, since potential entrepreneurs cannot invest in profitable occupations involving set-up costs. That limited access to financial markets can hinder the emergence of entrepreneurs is well documented empirically.<sup>1</sup> More recently it has also been shown that regulation-induced high costs of entry hamper firm creation (Klapper, Laeven and Rajan 2004) and lower the employment rate (Bertrand and Kramarz 2002, Fonseca, Lopez-Garcia and Pissarides 2001). However, very little attention has been paid to the determinants of entrepreneurship, i.e. the attitude of individuals who choose to be entrepreneurs. Yet, logically, this comes prior to the study of the obstacles to setting up a firm; furthermore, it is the lack of entrepreneurial attitude that is most often invoked to explain why underdeveloped areas do not take off.

---

<sup>1</sup>Evans and Jovanovic (1989) show that wealthier individuals who are currently employees are more likely than the less wealthy to become self-employed, a finding consistent with liquidity constraints. More recently, Guiso, Sapienza and Zingales (2004) use individual level data and differences in the ease with which external funds are obtained across Italian regions and find that in areas with a higher degree of financial development it is more likely that individuals become entrepreneurs, the rate of firm creation is higher, and there are more firms per inhabitant. Blanchflower and Oswald (1998) show that liquidity constraints affect the decision to become an entrepreneur even after controlling for individual ability.

Perhaps the best known recent model of entrepreneurship is that of Lucas (1978), explaining who in a given population will become an entrepreneur using differences in exogenously given individual talents. In Lucas “talent” is identified with the ability to extract output from a given combination of inputs. Thus, more talented individuals are those who can obtain a higher total factor productivity (TFP) if they start a business. Since individuals with more talent make more profits, they will choose to be entrepreneurs. But what can explain clusters if we do not believe in genetic differences, i.e. if the distribution of talents is the same across populations of individuals?

In this paper we consider two possibilities: differences in entry costs and differences in learning opportunities. One possibility is that there are heterogeneous costs of entry, and the locations with lower costs of setting up a firm end up with more entrepreneurs and more firms because even relatively less talented individuals will find it profitable to start a business. This line of reasoning (implicit in the literature on finance and entrepreneurship) constitutes the basic conceptual framework of government subsidies for entrepreneurship: the issue, accordingly, is how to enable potential entrepreneurs - those with the ability for the job - to actually set up a firm, either by removing obstacles (e.g. by making finance more readily available) or by lowering the entry costs (e.g. by reducing administrative compliance costs or eliminating costly regulation). To assess the potential of this explanation we extend Lucas’s model to include different costs of entry between locations and derive two implications: in equilibrium, in areas with lower entry costs *i*) there should be a larger share of entrepreneurs, and *ii*) their firms’ average TFP should be lower. Thus, in equilibrium there should be a negative correlation between the number of firms in a given location (for a given population) and their TFP. Also, the fraction of firms with TFP below a certain bound should be *positively* correlated with the density of firms in the location; above it they should be *negatively* correlated. We test these implications on a sample of Italian firms belonging to different clusters with varying numbers of firms and find them to be rejected by the data. Thus, differences in set-up costs alone cannot explain regional clusters.

Lucas’s model, however, takes the distribution of talents as exogenously given - perhaps a genetic feature - and ignores the possibility that entrepreneurial capabilities can be learned. The idea that individuals differ in their innate ability to become entrepreneurs is the same

as in Schumpeter (1911), where entrepreneurs are only the people who have the ability to innovate and entrepreneurship is not learnable because by definition the entrepreneur explores the unknown.<sup>2</sup> This may be why the generation of entrepreneurial talents has received relatively little attention in economic theory. Yet, it is plausible that entrepreneurial ability, broadly interpreted to include risk management, is, at least partly, learnable. Recent contributions to the theory of entrepreneurship (Rosenberg 1993, Baumol 1993) have stressed the role of incremental innovation and imitation in the diffusion of technological innovation for growth.<sup>3</sup> By this reasoning the Schumpeterian notion of entrepreneur should be extended to include the “imitative entrepreneur [...] as the person who is occupied in the transfer of technology or of other innovative ideas or procedures from one firm or one geographical location to another” (Baumol 1993, pp. 9-10). The concepts of imitation, adaptation and transfer have the idea of learning built in: before imitating or modifying something, one needs to learn it. This notion, therefore, opens up the possibility that entrepreneurial talents can indeed be learned.

We thus extend Lucas to include the possibility that entrepreneurial talents can differ across locations, possibly due to differences in learning opportunities. We show that in places with higher learning opportunities average entrepreneurial ability is higher and there are more entrepreneurs in relation to population. In contrast with heterogeneous entry costs, the model with heterogeneous learning opportunities implies that in equilibrium there should be a positive correlation between the share of entrepreneurs in a given location and their firms’ TFP, while the fraction of firms with TFP below (above) a certain bound should be negatively (positively) correlated with the density of firms. These correlations, which are the exact opposite of those predicted by the entry costs model, are precisely those found in the data. According to this empirical evidence, therefore, the standard practice

---

<sup>2</sup>Non-learnability is shared by the other modern explanation of entrepreneurship, formalized by Kihlstrom and Laffont (1979) and based on individual differences in attitudes towards risk. Since running a business is equivalent to the choice of a risky prospect, only the less risk-averse will become entrepreneurs. Furthermore, if tastes for risk are an innate feature of preferences, they cannot be learned. Though formally different from the Lucas ability model, a model with heterogeneous exogenous risk aversion would deliver similar implications. In an economy with a distribution of risky prospects (firms), with riskier prospects being also more profitable, less risk-averse individuals will invest in riskier firms which will be on average more productive. The marginal entrepreneur will be indifferent between being an employee with a fixed wage or investing in a risky firm.

<sup>3</sup>The role of entrepreneurs for the diffusion of knowledge has also been stressed by a recent paper by Audretsch and Keilbach (2005). They find support for this idea using German data.

of treating the distribution of potential entrepreneurs as exogenous, driven either by some specific ability or by some preference parameter such as risk aversion, is inconsistent with the data.

Our results bear important policy implications. First, consistently with McKenzie and Woodruff (2003) for Mexico, we de-emphasize entry costs in explaining regional differences in entrepreneurial activity, adding an important element to the debate on the barriers to entrepreneurship. Second, our findings indicate that the density of firms might be a fundamental driving force of local externalities. This result is not confined to Italy: Henderson (2003) finds a positive effect of the number of plants at the local level on productivity in the US.

Needless to say, a positive correlation between the TFP of the firms in an area and the number of firms located in that area may reflect the presence of local externalities that have nothing to do with the spread of information or the learning of managerial capacity. Following Marshall (1890), the literature on agglomeration economies has identified two alternative channels through which agglomeration (as measured by the number of firms) may affect firms' productivity: the size of the local work force, which can increase the division of labor and the quality of job-worker matches, and a greater variety of intermediate inputs. We address this issue empirically by controlling directly for the latter two channels, and the correlation between firm-level TFP and the number of firms survives the test.

The correlation between TFP and number of firms proves to be extremely robust to a series of controls, and the findings are consistent with this correlation being generated by causality running from the number of firms to productivity rather than the reflection of unobserved local factors driving both productivity and the number of firms. In fact, when the number of firms is instrumented with the local population in 1861, following an idea of Ciccone and Hall (1996), the estimates are very similar to those obtained with OLS. We further corroborate the explanation by testing some implications that are unique to the learning model. As predicted by the knowledge diffusion models of Jovanovic and Rob (1989) and Eeckhout and Jovanovic (2002), learning should be more relevant for small firms, and knowledge dispersion across firms should positively affect the amount of spillovers, thus increasing productivity. Both predictions are supported by the data.

One special implication of the learning model is that learning should occur mostly early on in an individual's working history. If this is the case, the number of firms in the early phase of an entrepreneur's career should affect his ability afterwards. Using a dataset with information on the earnings of entrepreneurs and their age, place of residence and place of birth, we find that entrepreneurs that grew up in areas with more firms at the learning age (assumed to be age 25) currently earn higher profits, even after controlling for the number of firms in the area where they are currently located. In this experiment, the contribution of the number of firms at learning age is identified not only by time series variation in the number of firms, but also (and mostly) by cross-sectional variation due to the mobility of entrepreneurs.

This paper relates to three strands in the literature. First, it is connected with the entrepreneurship literature based on entrepreneurial talent: we introduce and empirically support the concept that this talent is learnable. Second, it contributes to the agglomeration literature: we sort out competing explanations on the sources of local externalities. Finally, it is related to the productivity literature: we provide evidence of a new determinant of differences in TFP across firms. We provide evidence that differences in firm-level TFP may be due to the differing ability of entrepreneurs and that ability can be accumulated. If abilities were innate, then differences in the firm-level component of the Solow residual would simply reflect the distribution of the original endowment of talent, which would leave little hope of taking action to induce increases in TFP.

The rest of the paper is organized as follows. Section 2 sets out a simplified version of the Lucas model with exogenous factor prices, extended to incorporate the cost of setting up a firm. Exogenous and geographically heterogeneous costs of setting up a firm are a simple way to generate clusters. We then introduce the possibility of learning entrepreneurial ability while on the job and compare the predictions of the learning model with those of the set-up-costs model. We then empirically contrast a number of testable predictions from these two models, using Italian firm-level data matched with firm cluster information and described in Section 3. Section 4 presents our basic results, showing that, contrary to the pure set-up-costs model but in agreement with the learning model, entrepreneurial ability is greater where there are more entrepreneurs, and the probability mass on the left-hand side

of the empirical ability distribution is lower where there are more entrepreneurs. In Section 5 we explore the externality explanation of the correlation between the mass of entrepreneurs and their quality, finding evidence for a leaning externality. Section 6 extends the analysis to test some unique implications of the learning model and runs a number of robustness checks. Section 7 summarizes and concludes.

## 2 The model

We use a modified version of Lucas (1978) model of entrepreneurial ability. The economy consists of  $N$  regions, within each of which firms produce output using labor ( $n$ ) and capital ( $k$ ); the prices of the two inputs, denoted respectively  $w$  and  $u$ , are exogenously given and equal across regions. This assumption, which greatly simplifies the analysis, can be defended on the grounds that in our empirical analysis the territorial units are small enough to assume that they have no impact on aggregate factor prices and that factors are fully mobile.<sup>4</sup> Our conjecture is that with endogenous wages and user cost the results would still hold.

Given our partial equilibrium approach, we can confine the analysis to one representative region. We modify the basic model of Lucas by introducing a start-up cost  $c$  which has to be paid when becoming an entrepreneur. Individuals, who can be either entrepreneurs or employees, differ in entrepreneurial talent  $x$ ; the more talented can get more output from a given combination of labor and capital if they choose to run a firm. Entrepreneurial talents are drawn from a random variable  $\tilde{x}$  distributed according to a distribution function  $\gamma(x)$  over the support  $(\underline{x}, \bar{x})$ ,  $0 \leq \underline{x} < \bar{x} \leq \infty$ , with corresponding cumulative distribution function  $\Gamma(x)$ . Output is produced according to the production function  $xg[f(n, k)]$ , where  $f$  is a constant returns to scale function and  $g$  is a concave transformation. Following Lucas, we interpret this as the span of control. Define  $\phi(r) = f(n, k)/n$ , where  $r = k/n$ . The first

---

<sup>4</sup>Michelacci and Silva (2005) document that, in Italy, the share of entrepreneurs starting a business in the locality where they were born is substantially higher than the corresponding share of employees, arguing that becoming an entrepreneur requires some location-specific “relational” capital. This finding fully supports our modelling assumptions.

order conditions for an entrepreneur who maximizes profits can be written as:

$$\frac{\phi(r) - r\phi'(r)}{\phi'(r)} = \frac{w}{u} \quad (1)$$

$$xg'[n\phi(r)]\phi'(r) = u \quad (2)$$

from which it is immediately evident that the capital/labor ratio does not depend on  $x$ . The above FOCs give two equations in two unknowns, which can be solved implicitly to obtain two-factor demand functions in terms of entrepreneurial ability:  $n(x)$ ,  $k(x)$ . It is immediately verifiable that  $n'(x) > 0, k'(x) > 0$ .

## 2.1 Heterogeneous start-up costs

We now depart from Lucas. When becoming an entrepreneur, the agent pays a cost  $c$ . The profits of an entrepreneur of ability  $x$  before the entry cost are

$$\pi(x) = xg[n(x)\phi(r)] - n(x)[w + ur]. \quad (3)$$

Using the optimal input choices condition (1) and (2), we get  $\pi'(x) = g[n(x)\phi(r)] > 0$ : the profits of an entrepreneur are increasing with ability. An individual becomes an entrepreneur if  $\pi(x) - c \geq w$ . Given that  $\pi(x)$  is increasing, and that  $\pi(0) = 0$ , there exists one and only one value  $z$  at which the “marginal” individual is indifferent between being an entrepreneur and an employee:

$$\pi(z) - c = w \quad (4)$$

which implicitly defines the ability threshold value  $z(c)$  above which it is optimal to become an entrepreneur. In this economy, the mass of workers will be  $\Gamma(z)$  and that of entrepreneurs  $(1 - \Gamma(z))$ . By differentiating (4), we find that

$$\frac{dz}{dc} = \frac{1}{\pi'(z)} > 0 \quad (5)$$

The higher the start-up cost, the greater the ability of the marginal entrepreneur.

How can this model generate different levels of entrepreneurial activity across regions?

A first possibility is that regions differ in terms of entry cost  $c$ , say because of differences in bureaucratic costs due to disparate efficiency of the public administration. Areas with lower costs will have a larger share of entrepreneurs:

$$\frac{d(1 - \Gamma(z))}{dc} = -\gamma(z) \frac{dz}{dc} < 0 \quad (6)$$

Define the average entrepreneurial quality as the expected value of  $x$  conditional on being an entrepreneur:

$$E(x|x \geq z) = \frac{\int_z^{\bar{x}} x\gamma(x)dx}{1 - \Gamma(z)}. \quad (7)$$

When  $c$  rises, the quality of the marginal entrepreneur increases, hence so does average entrepreneurial quality:

$$\frac{dE(x|z)}{dc} = \frac{[E(x|z) - z]\gamma(z)}{[1 - \Gamma(z)]} \frac{dz}{dc} > 0 \quad (8)$$

where, to facilitate notation,  $E(x|z)$  stands for  $E(x|x \geq z)$ . The inequality follows from the fact that  $\frac{dz}{dc} > 0$  and  $E(x|x \geq z) > z$ , where the last inequality formalizes the notion that the marginal entrepreneur  $z$  is of lower quality than the average. Equations (6) and (8) imply that if differences in the share of entrepreneurs across locations are explained by entry costs, we should expect a negative correlation between the share of entrepreneurs and their average quality.

We can obtain additional implications of heterogeneity in entry costs for the distribution of entrepreneurial ability. Define  $\Omega(y|z)$  as the cumulative density function of the random variable obtained by truncating  $x$  at  $z$ :

$$\Omega(y|z) = \begin{cases} \frac{\Gamma(y) - \Gamma(z)}{1 - \Gamma(z)} & \text{if } y \geq z \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

$\Omega(y|z)$  is the share of entrepreneurs below any given level of ability  $y$ . As  $c$  increases, this

share falls:

$$\frac{d\Omega(y|z)}{dc} = -\frac{\gamma(z)(1-\Gamma(y))}{(1-\Gamma(z))^2} \frac{dz}{dc} < 0 \quad (10)$$

This implies that heterogeneous entry costs induce a positive correlation of the share of entrepreneurs below any given level of ability with the overall mass of entrepreneurs, and a negative correlation above that level.

Summing up, heterogeneity in entry costs generates two sharp predictions: a larger mass of entrepreneurs should be associated with *i*) lower overall quality and *ii*) with a larger (smaller) share of entrepreneurs below (above) any quality level.

## 2.2 Heterogeneous costs of learning entrepreneurial skills

A second potential reason for different levels of entrepreneurial activity across locations is that in some areas it might be easier to learn entrepreneurial skills. This may be due to the fact that in some locations the diffusion of knowledge and ideas is facilitated by environmental factors. As shown by Jovanovic and Rob (1989), the easier the circulation of knowledge the higher entrepreneurial quality. To model this possibility and derive its implications, we assume that the distribution of talent is parameterized by a shift factor  $\lambda$ , specific to each location:  $x \sim \gamma(\cdot, \lambda)$ , with  $\Gamma(x, \lambda)$  representing the cumulative distribution function. The parameter  $\lambda$  represents the possibility of learning that characterizes each location. Of course,  $\lambda$  might be any shifter of the distribution of talents. Distinguishing learning from other possible explanations will be the main task of the empirical analysis. We assume that  $\partial\Gamma/\partial\lambda < 0$ :  $\lambda$  shifts the probability distribution to the right in the first order stochastic dominance sense. In this setting, clusters arise in areas with high  $\lambda$ :

$$\frac{d(1-\Gamma(z, \lambda))}{d\lambda} = -\frac{\partial\Gamma(z, \lambda)}{\partial\lambda} > 0. \quad (11)$$

Equation (11) implies that the higher  $\lambda$ , the larger the share of individuals with a given talent above the threshold  $z$ , and so the larger the mass of entrepreneurs.

As before, we define average entrepreneurial quality as the expected value of  $x$  condi-

tional on being an entrepreneur. This value will now depend on  $\lambda$ :

$$E(x|z, \lambda) = \frac{\int_z^{\bar{x}} x\gamma(x, \lambda)dx}{1 - \Gamma(z, \lambda)}. \quad (12)$$

The effect of a change in  $\lambda$  on average entrepreneurial quality is<sup>5</sup>:

$$\frac{dE(x|z, \lambda)}{d\lambda} = \frac{[\int_z^{\bar{x}} x \frac{\partial \gamma}{\partial \lambda} dx - E(x|z, \lambda) \frac{\partial(1-\Gamma(z, \lambda))}{\partial \lambda}]}{(1 - \Gamma(z, \lambda))} \quad (13)$$

Given that the first term is positive<sup>6</sup> and the second negative, this expression cannot be signed a priori. In fact, an increase in  $\lambda$  has two contrasting effects on average ability: on one side, for given  $z$ , it shifts ability to the right, i.e. increases average ability; on the other, some agents that would have been employees for a lower  $\lambda$  now become entrepreneurs. Given that they enter at the lower end of the talent distribution, more ‘entry’ implies that quality is diluted, thus reducing average quality - the second term in square brackets in (13). The sign of  $\frac{dE(x|z, \lambda)}{d\lambda}$  depends on the shape of the distribution of talents and on how  $\lambda$  parameterizes it. However,  $\frac{dE(x|z, \lambda)}{d\lambda} > 0$  holds for a general family of distributions, the log-concave distributions (Barlow and Proschan 1975).<sup>7</sup> This family of distributions includes, among others, the uniform, the normal and the exponential. For such distributions, a positive correlation between the share of entrepreneurs and their average quality will emerge.<sup>8</sup>

The same reasoning applies to the distribution of entrepreneurial talents conditional on  $x \geq z$ ,  $\Omega(x|z, \lambda)$ : as before, while not determined a priori, the mass of entrepreneurs with talent below (above) an arbitrary threshold  $y$ ,  $\Omega(y|z, \lambda)$  can decrease (increase) with the density of firms. Therefore, with learnable talent, under some conditions on the distribution function  $\Gamma$  there can be a positive relation between the overall share of entrepreneurs and their quality.

---

<sup>5</sup>This model does not consider the choice of how much to invest in learning. In the appendix we show that it is straightforward to endogenize the learning decision and arrive at the same conclusions.

<sup>6</sup>Using the property of first order stochastic dominance, it can be shown that  $\int_z^{\bar{x}} x \frac{\partial \gamma}{\partial \lambda} dx > 0$ . In fact, for  $d\lambda > 0$ , stochastic dominance implies that  $\int_z^{\bar{x}} x\gamma(x, \lambda + d\lambda)dx > \int_z^{\bar{x}} x\gamma(x, \lambda)dx$ . Grouping terms and taking the limit for  $d\lambda \rightarrow 0$  delivers the result.

<sup>7</sup>A function  $h$  is said to be log-concave if its logarithm  $\ln h$  is concave, that is if  $h''(x)h(x) - h'(x)^2 \leq 0$ .

<sup>8</sup>The log-normal, traditionally used to model firm size (Steindl 1990) and income distribution (Harrison 1981), does not satisfy this property. Some simulations indicate that even for this distribution the above condition will generically be satisfied, implying that average ability increases with the number of firms.

To sum up, a model with different entry costs predicts a negative correlation between the number of entrepreneurs and their quality, while a model where talents can be acquired is compatible with a positive correlation, and under some conditions on the primitive distribution of talents will deliver it. We will further refine this interpretation and contrast it with possible alternatives in the subsequent sections where we confront the implications of the model with the data.

### 3 Data description

We test our propositions drawing on a dataset of Italian firms, the Company Accounts Data Service (in Italian, “Centrale dei Bilanci”, CB), which provides standardized data on the balance sheets and income statements of about 30,000 Italian non-financial firms plus information on employment and firm characteristics. Data, available since 1982, are collected by a consortium of banks interested in pooling information about their clients. A firm is included if it borrows from a bank in the consortium. The focus on level of borrowing skews the sample towards larger firms. Furthermore, because most of the large banks are in the northern part of the country, the sample has more firms headquartered in the North than in the South. Finally, since banks are interested in creditworthy firms, those in default are not included, so the sample is biased towards better-quality borrowers. Despite these biases, previous comparisons with population moments indicate that the sample is not too far from being representative; moreover, it covers more than half of private sector sales (Guiso and Schivardi 1999). Table 1, Panel A, gives summary statistics on employment, value added and the stock of capital at constant prices for the 1991 CB sample comprising 16,885 observations; we use 1991 as the reference year for our regressions but check for robustness when all the available years are used. Data are reported by industrial sector using a 10-industry classification; to avoid the usual problems of estimating productivity in services we have restricted the analysis to manufacturing.<sup>9</sup> The capital stock is constructed using the permanent inventory method with sectoral deflator and depreciation rates (see

---

<sup>9</sup>As will become clear in the next subsection, the sectoral classification balances the need for homogeneity of the production technology and that of a sufficient number of sectoral observations to properly estimate TFP.

Cingano and Schivardi (2004) for details).

We complement the CB data with another dataset on Italian industrial clusters, the Local Labor Systems dataset. The territory of Italy has been divided by the National Statistical Institute (ISTAT) into 784 local labor systems (LLS) on the basis of working-day commuting areas.<sup>10</sup> The idea behind the algorithm is to define self-contained labor markets in terms of worker mobility. As such, this is the correct geographical boundary for an environment within which learning takes place and learning relations are formed. Since the Data Services gives the firm's LLS code, we can match firms with the corresponding LLS. The resident population of each LLS comes from the census while the number of manufacturing firms in the LLS is obtained from the files of the Italian Social Security Administration (INPS) on the population of firms with at least one employee for the years 1986-98. With respect to CB, the information on firms is much less detailed: for example, output is not reported so that TFP cannot be computed. For our purposes, the database contains the number of employees, the sector and the location of each firm, from which very precise measures of industrial density at the local and sectoral level can be constructed. Panel B shows summary statistics on the average number of firms per LLS for each of our 10 industries. It is clear that there is considerable geographical variation in the clustering of industry: for all industries, there are 92 firms per LLS with a standard deviation almost three times the mean (269) and range of 1-8,392. Figure 1 gives a visual picture of the geographical clustering of entrepreneurship and its dispersion across local labor systems. Although the largest clusters are mostly in the North, there are several in the South. However, to make sure that our results are not driven by North-South differences, in our empirical analysis we always include area dummies.

Finally, from the last seven waves of the Survey of Household Income and Wealth we obtain data on the earnings of individual entrepreneurs which we use in Section 6 to test whether the number of firms at "learning age" affects current entrepreneurial income, as predicted by the learning model. The survey is run bi-annually by the Bank of Italy on

---

<sup>10</sup>Even if defined using the same criteria (commuting ties), the concept of LLS differs from US Core Based Statistical Areas since there is no minimum population requirement. Hence, like the French "zones d'emploi", the Italian LLS entirely and continuously cover the national territory. The average land-area is 384 square kilometers, with a population density of 188 inhabitants per sq. km. Population ranges from 3,000 in the smallest LLS to 3.3 million in the largest.

a representative sample of about 8,000 households and their components. It contains information on various sources of earnings as well as a rich demographic description of the survey participants. We select all entrepreneurs and extract information on their province of residence and birth and their demographic characteristics. We then assign to each entrepreneur in the sample (1,213 observations) the number of firms in the province where he/she was located at age of learning (age 25) and the number of firms in the province where his/her activity is currently located, both obtained from census data.

### 3.1 Estimating entrepreneurial ability

In order to test the two alternative models described in Section 2 first we need a measure of entrepreneurial ability at the firm level. In Lucas, entrepreneurial ability is modeled as a shift in the production function: better entrepreneurs will get more output from any combination of inputs. Put in this way, entrepreneurial ability is simply equivalent to a firm's TFP. If this were the only feature affecting a firm's TFP, Lucas's model might serve as the basis for a theory of TFP, or at least of its dispersion across firms. The main limit of this theory is that the dispersion is simply assumed and inherited from the differences in entrepreneurial ability, which is taken as given. Our model of learning is a way of providing a basis for an endogenous explanation of firm-specific TFP and the determinants of differences in average TFP across locations. To compute the contribution of entrepreneurial ability to TFP we assume that a firm's TFP has two components: one is common to all firms in the same industry and depends on their specific technology. The second is firm-specific, and in the spirit of our model we assume it reflects the ability of the firm's entrepreneur.

To obtain an estimate of the TFP of firm  $i$  we assume that output is produced with a Cobb-Douglas production function of the form  $Y_{si} = x_{si}A_s * K_i^\alpha L_i^\beta$ , where  $s$  indexes the industry,  $Y$  is output, and  $K$  and  $L$  denote the stock of capital and labor services. TFP is given by  $TFP_{si} = x_{si}A_s$ , and is the product of the sectoral component,  $A$ , and the firm-specific component,  $x$ . The latter is our measure of entrepreneurial ability. To obtain an estimate of TFP we need to compute values for  $\alpha$  and  $\beta$ . To obtain estimates of the production function parameters that are robust to the endogeneity of some of the inputs (capital accumulation and labor demand may respond to unobserved productivity shocks)

and the selection induced by exit (with some irreversibility, leaving the industry is more likely for firms with a lower capital stock when a bad productivity shock occurs) we use the multi-step estimation algorithm proposed by Olley and Pakes (1996), which accounts for both problems, allowing for consistent and unconstrained estimation of  $\alpha_s$  and  $\beta_s$ .<sup>11</sup> To assess the reliability of the estimates, we also calculate the coefficients using Solow’s assumptions.

Table 2 reports the estimated values of  $\alpha_s$  and  $\beta_s$  with the two procedures. Production function estimates of  $(\alpha_s + \beta_s)$  lie in the range 0.93-1.05. The model assumes decreasing returns to scale to avoid a degenerate equilibrium in which there exists only one firm supplying the whole market. Given that the capital coefficient is estimated using a semi-parametric procedure, we obtained its standard errors through a bootstrapping exercise based on 150 replications. As in Olley and Pakes (1996), standard errors are relatively large<sup>12</sup> and, given that the estimates of  $(\alpha_s + \beta_s)$  are always somewhere around 1, the empirical model has no power to discriminate between different degrees of returns to scale. Formally, the null hypothesis  $(\alpha_s + \beta_s) < 1$  is never rejected in a one-sided test even at the 10 per cent confidence level.<sup>13</sup> In terms of single coefficients, compared with Solow’s method the Olley and Pakes (1996) procedure tends to result in a higher coefficient for labor and a lower one for capital, arguably because of deviations of the factor markets from the competitive paradigm; apart from these differences, the two methods give broadly consistent results. In what follows, we use the TFP estimates obtained with the Olley and Pakes procedure to recover our measure of entrepreneurial ability.

Table 3 describes the distribution of our estimate of  $x$ , obtained by removing the industry-level component with a first-stage regression of estimated TFP on a set of industry dummies. To account for possible outliers we drop observations in the first and last

---

<sup>11</sup>To summarize, the procedure controls for endogeneity by approximating the unobserved productivity shocks with a non-parametric function of observable variables and for selection by introducing a Heckman-type correction term.

<sup>12</sup>Pakes and Olley (1995) discuss the asymptotic properties of the estimator, suggesting that the bootstrapping procedure might overestimate the true standard deviation of the capital coefficient, partially explaining why its values are higher than those for labor.

<sup>13</sup>Indeed, returns to scale might be initially increasing, due for example to fixed production costs, so that the “span of control” only kicks in for larger levels of operation. In fact, some small, growing firms might still be on the increasing part of the production function but, due to convex costs of adjusting the scale of operation, might not immediately exploit the full advantages of scale.

percentile of the ability distribution by year-sector. The sample mean of entrepreneurial ability is 2.35 but there is considerable dispersion, as the high value of the standard deviation (0.5) implies. When the sample is split according to the density of firms in each geographical unit, entrepreneurial ability is higher where firms' density is above median than where it is below median (2.39 compared to 2.20), which is inconsistent with the start-up cost hypothesis but not with the learning hypothesis. The table also shows the share of firms with ability below the 25<sup>th</sup> and above the 75<sup>th</sup> percentile both for the total sample and the two sub-samples of high-density and low-density areas. Contrary to the start-up cost model, there is a larger frequency mass to the left of the lower threshold in places with fewer firms (36 per cent in the low-density group compared with 22 per cent among the high-density locations) while in accordance with the learning hypothesis the probability mass to the right of the upper threshold (the 75<sup>th</sup> percentile) is greater where there are more firms for given population. Thus, the descriptive evidence clearly rejects the start-up cost theory in favor of learning. The same conclusions can be drawn from Figure 2, which shows the distribution of entrepreneurial ability for firms in high-density and low-density local labor systems, computed using Gaussian kernel non-parametric smoothers evaluated at 25 points over the range of  $x$ . Notably, the distribution of entrepreneurial ability is shifted to the right in areas with a high density of firms, implying that entrepreneurs in high-density areas have greater ability. In the following sections we refine this descriptive evidence using formal regressions testing for statistical significance and controlling for any additional effects. Table 2 also reports summary statistics for some of these controls, such as the number of firms in the LLS and that in the LLS and industry, the number of workers in the LLS and the cumulated stock of capital in the LLS. Not surprisingly, in high-density areas there are also more workers and capital stock is larger.

#### **4 Start-up costs or entrepreneurial learning? Testing the two models**

According to equations (6) and (8), the start-up cost model implies that as we vary entry costs, entrepreneurial ability and the mass of entrepreneurs should move in opposite direc-

tions. Under reasonable assumptions, the entrepreneurial-learning model implies a positive correlation between the two variables. Table 4 reports our basic test; the left-hand side is the log of our estimate of entrepreneurial ability ( $x$  in the model); on the right-hand side we include the share of entrepreneurs, i.e. the ratio between the number of firms, obtained from the yearly INPS archives, and the resident population in the local labor system, obtained from the population census ( $1 - \Gamma(z)$  in the model), a variable we call Entrepreneurial Incidence (EI). We also include as controls three geographical dummies for the Centre, Northeast and Northwest of the country (the South is the omitted region). Given that the independent variable only varies across LLS-year, we use standard errors adjusted for clustering. To check the robustness of our results, we use three different samples: a single cross section in 1991, which is the Census year when the population is counted; the de-trended firm average over the entire period<sup>14</sup> and the full panel with year dummies. The first column shows the estimates using the 1991 cross-section; the correlation between EI and TFP is positive and statistically significant at 10%; to give a sense of its magnitude, an increase in EI of one standard deviation would bring about an increase in TFP of a little more than 2%. Using firm averages and pooled data (columns 2 and 3), the estimates are slightly higher and much more precise. This clearly contradicts the start-up cost model of cluster formation already questioned by the previous descriptive evidence. This result is very robust across specifications.

To control for unobserved factors at the local level, we run the regressions including province dummies, a very fine geographical control.<sup>15</sup> The coefficient is slightly lower, an indication of possible spatially correlated effects, but still positive and statistically significant in two cases out of three.

The second panel of Table 4 sharpens the evidence on the validity of the start-up cost theory by looking at the relations between the number of firms in a cluster and the share with ability below a lower bound or above an upper one. According to this model, there should be a positive (negative) correlation between the number of firms and the frequency of

---

<sup>14</sup>According to Bertrand, Duflo and Mullainathan (2004), the serial correlation in the independent variable can make inference problematic. As a simple solution, they propose running estimates on the collapsed data and ignoring the time series variation.

<sup>15</sup>Italy has 103 provinces, so that there are 8 LLS per province.

firms with ability below (above) a certain bound. The intuition is that as the start-up cost declines and the number of firms increases, the new entrants are of lower quality, so there is a larger (smaller) mass of entrepreneurs with ability below (above) any given threshold. To test this implication we set the lower bound at the 25<sup>th</sup> (and the upper at the 75<sup>th</sup>) percentile of the empirical distribution of ability and construct an indicator that is equal to 1 if the firm's specific ability is below (above) the threshold. We then run a probit estimate on the entrepreneurial share and the geographical controls. The first three columns of Table 4 show the results for the share above the 25<sup>th</sup> percentile for the three samples, using macro areas as geographical controls. They reveal a negative correlation, with highly significant coefficients. This pattern is broadly confirmed when provinces are used as geographical controls (last three columns). The last panel shows the share of firms above the 75<sup>th</sup> percentile, finding a positive coefficient of the number of firms scaled by population, albeit significant only for the pooled sample. Taken together, these findings suggest that a larger share of firms is associated with a shift to the right in the distribution of entrepreneurial talent. Thus, the two main implications of the start-up cost model are strongly rejected by the data. On the other hand, they are consistent with the learning model, which (under mild conditions) not only predicts a positive correlation between ability and the share of entrepreneurs in the population, but also a negative correlation between the share of firms with ability below a lower bound and the entrepreneurial share in a cluster (and vice versa for the right tail).

The evidence in Table 4 is unequivocal: it strongly rejects theories of cluster formation based only on differences in entry and start-up costs, such as differences in the fixed costs or bureaucratic steps required to organize a firm. It lends support to models that emphasize differences in the opportunities individuals have to accumulate entrepreneurial abilities, i.e. to acquire the particular skills needed to set up and run a business.

To further strengthen our interpretation, we consider the correlation between EI and TFP at the local sectoral level. If differences in entrepreneurial incidence are due to entry costs, then they should apply independently of the sector of activity, so that the correlation should arise at the aggregate level.<sup>16</sup> Instead, we should expect learning to have a strong

---

<sup>16</sup>This is not to say that entry costs are equal across industries. Rather, it means that if two locations

sectoral component.<sup>17</sup> In fact, entrepreneurship entails some degree of specificity. Thus, if learning is more important within an industry than across industries (due to some kind of specificity) then the correlation between the share of firms and entrepreneurial ability should be stronger in the same LLS and industry than overall. This is tested in Table 5, where we insert both the overall entrepreneurial share and that at the sectoral level, i.e. calculated using the number of firms in an LLS-industry. The first panel shows the results for the correlation between ability and the two indexes of entrepreneurial share. We always find that the effect is stronger and the significance higher for the industry-level index, independently of sample and type of geographical controls.

The second and third panels report the regressions for the probability that the firm has a specific component of TFP below the 25<sup>th</sup> percentile of the distribution (Panel B) and above the 75<sup>th</sup> percentile (Panel C). The pattern is very similar to that found in Panel A, with two exceptions for the first indicator, for which the overall share is sometimes significant. All in all, the evidence suggests that location-industry factors underlie the correlation, consistently with the learning hypothesis and at odds with the idea that some locations have more firms because of lower start-up costs.

## 5 Entrepreneurial ability and local externalities

Up to now, we have used the model to obtain equilibrium correlations between EI and ability, without any causal interpretation. We now take a further step and investigate the causes. In practice, by log linearizing (12), we can immediately verify that this amounts to identifying some measurable factors that shift the ability distribution (the variable  $\lambda$  in the model) and to running a regression of (log) ability on the (log) indicator of  $\lambda$ . The logical candidate to explain productivity differences according to density is local externalities. In this section, therefore, we contrast different sources of externalities to look for more direct evidence for or against the learning hypothesis.

---

differ in the level of such costs, the differential effect on EI should be uniform across industries.

<sup>17</sup>There is a large literature on the relative importance of intra-industry and inter-industry knowledge spillovers, which has so far failed to reach a clear consensus, even if the intra-industry component tends to be important in most empirical studies (Rosenthal and Strange 2004). Using the same dataset as in this paper, Cingano and Schivardi (2004) find evidence in favor of intra-industry spillovers, and no evidence of inter-industry.

There is a large theoretical literature on agglomeration economies (see Duranton and Puga (2004) for a recent survey). This literature has maintained the original Marshallian idea (Marshall 1890) that the spatial concentration of production can be beneficial for three reasons. First, concentration fosters the circulation of ideas and the possibility of learning from other agents. Second, a large concentration of workers in the same industry can have beneficial effects both in terms of the specialization that each worker can achieve and the quality of worker/job matches. Third, industrial clusters offer a wide variety of intermediate inputs, with potentially beneficial effects on productivity.<sup>18</sup> The empirical literature on the extent and scope of agglomeration economies suggests that localization economies are important. However, a consensus has not yet emerged on the relative merits of the different sources and investigation is continuing (see Rosenthal and Strange (2004) for an exhaustive assessment of the state of the empirical debate).

We distinguish among these different effects by proposing a proxy of each potential externality. To proxy for learning externalities we use the number of firms operating in a given industry and in a given area. If learning entrepreneurial abilities is not, as we argue, a routine activity, then an obvious feature facilitating learning is the number of firms in a given location. If learning takes place mainly on the job and on the site, a larger number of firms offers more (and better) opportunities to acquire entrepreneurial abilities, since a potential entrepreneur can compare different working practices and business ideas, possibly by working in different firms.<sup>19</sup> Moreover, the process of knowledge acquisition continues even after the business is started, because knowledge spillovers on alternative technologies or new markets keep accruing in regions with a large population of firms. The

---

<sup>18</sup>Marshall (1890) wrote: “When an industry has thus chosen a locality for itself, it is likely to stay there long: so great are the advantages which people following the same skilled trade get from neighborhood to one another. The mysteries of trade become no mysteries; but are as in the air, and children learn many of them unconsciously.... Employers are apt to resort to any place where they are likely to find a good choice of workers with the special skill which they require. .. The advantages of variety of employment are combined with those of localized industries in some of our manufacturing towns, and this is a chief cause of their continued economic growth”.

<sup>19</sup>According to Saxenian (1994), the mobility of workers across firms and their acquired capacity to start up new firms was one of the main reasons behind the success of Silicon Valley during the technology boom. This would also be consistent with the model and the empirical evidence of Lazear (2002), according to which the probability of becoming an entrepreneur is positively related to the number of tasks a worker is previously exposed to, because the entrepreneur needs to be able to understand and coordinate different activities: again, more firms could offer better opportunities of learning the complex set of skills required to manage a firm.

availability of intermediate inputs - the second reason why spatial concentration can raise firms' productivity - is easily measured by the ratio of intermediate inputs to value added at the local sectoral level. In fact, if greater concentration leads to higher productivity through more reliance on intermediate inputs,<sup>20</sup> we should find that TFP is positively related to this indicator. The third reason, labor market pooling effect, is measured by the number of workers operating in a given LLS-sector. Summary statistics for these variables are reported in Table 3.

In Table 6, Panel A, we regress firm-level TFP on the number of firms, the share of intermediate inputs over value added and the number of workers in the LLS-industry (all variables are in logs).<sup>21</sup> With four spatial controls, we find that the number of firms has a positive and significant coefficient in all specifications, with a value of around 0.05. The share of intermediate inputs is not significantly different from zero in the cross-sections, but is significant when using averaged data and in the pooled data, and thus there are indications that the availability of intermediate inputs might also foster local productivity, though the evidence is less clear-cut than for the number of firms. The number of workers is never significant, save in one case. The exception is the pooled data with 4 spatial controls, and its negative coefficient is at odds with the idea that local externalities are attributable to labor market pooling effects. To give a sense of the magnitude of these effects, using the pooled estimate of column 3 we calculate that increasing the number of firms by one standard deviation would bring about an increase in firms' productivity of about 9 per cent, which is quite large; doing the same with intermediate input intensity would increase TFP by a more modest 1.2 per cent. The last three columns of Table 6 repeat the exercise with 103 spatial controls (the provinces). The estimates for the number of firms and the intermediate inputs become somewhat smaller, but remain highly significant. The number of workers has no effect in any specification.

These patterns are confirmed by the analysis of the TFP percentiles. The second panel shows the regressions for the probability that the firm-specific component of TFP falls below

---

<sup>20</sup>Using US data, Holmes (1999) finds that sectoral concentration at the local level is positively related to intermediate input intensity, although the effect is rather modest.

<sup>21</sup>While the number of firms and that of workers can be computed from the INPS dataset, and therefore cover the respective populations, we have information on intermediate inputs and value added only for the CB sample, which is therefore used to compute the measure of intermediate input intensity.

the 25<sup>th</sup> percentile of the distribution. The number of firms has a negative effect, as predicted by the learning model, and its coefficient is statistically significant in all specifications. The intermediate input indicator is also negative, although again less precisely estimated, and the labor market pooling indicator is marginally significant in only one case. The last panel shows the estimates for the probability that firm-specific TFP exceeds the 75<sup>th</sup> percentile of the distribution, with results very much in line with the previous ones. Here, the intermediate inputs indicator is always significant while the number of workers is either insignificant or negative.

Table 6 shows conclusively that the relationship between entrepreneurial ability and the number of firms is robust to controls for other potential sources of local externalities. Moreover, its effects are more precisely estimated and economically more important than those of the alternative sources; the evidence that the availability of intermediate inputs at the local level has a positive impact on TFP is weaker, and no evidence of labor market pooling emerges from the data.

## 6 Robustness and further implications

### 6.1 Dealing with unobserved heterogeneity

Having established that the number of firms is strongly correlated with firm-level TFP, we still face the problem of endogeneity that plagues the empirical analysis of density and productivity. There could in fact be unobserved local factors, not accounted for by our geographical controls, as even the finer ones (the province dummies) refer to wider areas than the Local Labor System. For example, politicians might care about places with a high production density and provide business-oriented public goods, such as infrastructure, which raise productivity. While the province dummies absorb some of these effects, the transfers could take place at an even finer geographical level, leaving the regression residual correlated with a firm TFP. We address this issue in two ways. First, since in the estimates in Table 6 our regressors vary with the LLS and the industry, we can exploit the cross-industry variation while inserting geographical controls at the LLS level. In Table 7 we report the same regressions as in the previous one, adding dummies for the 784 LLS dummies. We

find results that are similar to those of Table 6 with province dummies, losing significance only in the case of the cross-section sample. Similar conclusions are reached with the probit estimates in Panel B and C. Indeed, in a similar vein, Henderson (2003) finds a positive and robust correlation between number of plants and productivity in the US.<sup>22</sup> His findings therefore suggest that the correlation we find is not confined to Italy.

Second, we provide instrumental variables estimates. As an instrument for the number of firms, we need a variable that is correlated with the number of firms in a location but not with firm-level productivity in our sample. Following Ciccone and Hall (1996), we use as instrument the population at the LLS level in 1861 (the first Italian census). Clearly, the larger the population in a given location, the larger the number of firms, even if the primitive distribution of abilities is the same across areas. Moreover, given that location choices are persistent, due to moving costs and preference for “home”, it can be maintained that population in 1861 is correlated with population today and thus with today’s mass of firms. Indeed, a regression of the log of number of firms at the LLS-industry level on the population in 1861 at the LLS level produces an  $R^2$  of 0.4. On the other hand, it is reasonable that local population size in the mid- 19<sup>th</sup> century is not correlated with potential determinants of productivity in industry over our sample period. This is our identifying assumption; it can be defended on the grounds that the industrial revolution in Italy did not even begin until the 1890s and that the biggest wave of industrialization occurred in the 1950s. If we presume that location choices before the industrial revolution were dictated mainly by agricultural fertility, and that this has no obvious relation to productivity in manufacturing in the later 20<sup>th</sup> century, then the instrument satisfies the exogeneity condition.

Table 8 reports the results of a regression of firm efficiency on the number of firms in the LLS-sector, estimated by OLS (first three columns) and by IV (last three columns). For brevity, we only report the results with using provincial dummies as geographical controls. In Panel B and C we estimate a linear probability model to avoid the problems of IV

---

<sup>22</sup>Henderson’s paper belongs to the literature assessing the industrial scope of spillovers, i.e. whether they are within or between industries, and he uses the number of own-industry plants as a measure of industrial concentration. Given that he does not aim at separating different sources of externalities, unlike us he does not control for the alternative channels. In line with what we find, he claims that the number of plants is the most robust indicator of intra-industry spillovers, and interprets it as evidence of knowledge externalities.

estimates with probit models. All the regressions indicate that OLS and IV estimates are highly similar, with no evidence of a systematic bias in the OLS regressions. This suggests that our geographical controls are fine enough to capture any local factor that affects firms' TFP and could be correlated with the number of firms in the area, lending support to our causal interpretation.

We have also performed robustness checks along the industry dimension. First, the two-digit classification we use might be too coarse and mix industries with different characteristics. While a more refined analysis is difficult because of limited sample size, particularly in the estimate of the production function coefficients, we can increase the number of industry controls in the baseline regression. We have run the basic regression on the pooled data including 296 dummies at the 4-digit level, finding no substantial difference in the estimates. A second problem is that we impose the same coefficient for the number of firms across different industries. While assessing learning opportunities at the industry level is beyond the scope of this paper, we have run a separate regression for each industry. In all industries we find that the number of firms has a positive and significant effect on TFP, with coefficients ranging from a low of 0.017 for basic metal to a high of 0.067 for leather and footwear.

## 6.2 Is the number of firms proxying for learning opportunities?

Having established that the link between firm level TFP and the number of firms is likely to be a causal one, we want to corroborate the interpretation in terms of learning opportunities and knowledge spillovers. For example, the number of firms could be a proxy for competition, which would result in a selection increasing the productivity of the survivors.<sup>23</sup> For learning externalities, we rely on specific theoretical predictions. Unfortunately, as noted by Duranton and Puga (2004), rigorous theoretical work on knowledge spillovers is rather scant. To our knowledge Jovanovic and Rob (1989) and Eeckhout and Jovanovic (2002)

---

<sup>23</sup>This effect is often referred to in the literature as the “Porter effect”, following Porter (1990) who studies the highly competitive and successful tile industry centered around Bologna in Italy. Syverson (2005) builds a model of the selection effect based on demand density and transportation costs, and tests it with data for the ready-mix concrete industry in the US, finding supporting evidence. A similar effect also emerges in the matching model of Lagos (2004).

are the only models that offer testable theoretical predictions.<sup>24</sup> The key to these models is that learning requires differences in knowledge among agents: if everybody knows the same thing, then there is no benefit from knowledge diffusion. This idea has two important implications that we can easily test with our data:

1. The least informed agents should gain more from spillovers, i.e. their productivity should be more sensitive to the amount of knowledge that can be accessed locally;
2. The dispersion of knowledge among firms should have a positive impact on productivity, because there is more to gain from knowledge diffusion.

We can test the first prediction by allowing the coefficient of the number of firms (our measure of potentially accessible knowledge) to differ across firms with different levels of knowledge. We therefore interact the number of firms with a dummy variable (“small”) that is equal to 1 if the firm’s capital stock is below the sample median, calculated at the LLS-industry level in each year, and add this interaction term to the regressions. The results, reported in Table 9, are strongly supportive of this prediction. In the OLS regressions, the elasticity of TFP to the number of firms is between 50 and 100 per cent higher for small firms across the different specifications. The increase in the estimates is very similar for the probability of being above the 75<sup>th</sup> percentile and only slightly smaller (in absolute terms) for that of being below the 25<sup>th</sup> percentile. Remarkably, the difference is significant at 1 percent in all 18 specifications, an indication of its robustness.<sup>25</sup>

To test the second implication, we need a measure of knowledge at the firm level. Following Eeckhout and Jovanovic (2002), we use the capital stock as a proxy of firm-level knowledge. First, the stock of capital is a measure of size, and it is reasonable to assume that larger firms have a higher stock of knowledge; second, insofar as knowledge is embodied in capital, it will be captured by this measure. We compute the standard deviation of the

---

<sup>24</sup>A related literature studies the diffusion of skills at the worker level - see Moretti (2004) for a survey. By studying the evolution of migrants’ wages, Glaeser and Maré (2001) find evidence that cities favour the accumulation of human capital rather than simply increase individual productivity due to some thick-market externality.

<sup>25</sup>As a further unreported check, we have also used an interaction between the capital stock and the number of firms, to avoid the arbitrariness of the split point of the regressions in Table 9. We find that the interaction is always negative (positive for the probability of being below the 25<sup>th</sup> percentile), indicating that the larger the firm’s stock of knowledge is the smaller is the effect of the number of firms.

capital stock at the level of LLS-industry in each year, and use its log as an additional regressor. Table 10 reports the results of this set of exercises. For the OLS regressions, we find an elasticity of TFP to knowledge dispersion of about 0.04 (with higher values for the pooled regressions) and high levels of statistical significance. This finding is confirmed by the probit estimate, again more markedly for the probability of being above the 75<sup>th</sup> percentile of the TFP distribution.

We have experimented with different measures of dispersion, using the ratio of the 90<sup>th</sup> to the 10<sup>th</sup> percentile of the capital stock, controlling for outliers and using a different functional form (i.e. in levels rather than in log), and alternative measures of firms' size, such as employment level. Again, results proved to be remarkably robust to all these changes. We conclude that, in line with theoretical predictions, knowledge dispersion has a positive effect on TFP. This is consistent with higher productivity levels being related to knowledge spillovers and learning externalities, and at odds with the competition effect, which should imply a negative impact of dispersion on productivity.

Taken together, the empirical exercises provide a compelling argument that differences in productivity across locations are at least partly due to the different learning opportunities and knowledge spillovers.

### **6.3 Accumulated abilities and entrepreneurial profits**

One alternative way of testing the learning model is to rely on the idea that entrepreneurial performance should depend on *accumulated* abilities, once personal characteristics, such as age, education and current externalities have been controlled for. One important aspect is that the accumulation of abilities occurs throughout one's working history and learning could be more pronounced in the early phase of the career. If this were the case, then the entrepreneurs that grew up in areas and periods with higher learning opportunities should be, *ceteris paribus*, more able than the others. This suggests another way to test the learning model versus alternative spillover mechanisms, i.e. to consider, in addition to the current number, the number of firms where the entrepreneur was located in the early phase of his/her working career.

To perform this test we use data from the last seven waves (1989, 1991, 1993, 1995, 1998,

2000 and 2002) of the Survey of Households' Income and Wealth and select all individuals who, at time of interview, classify themselves as entrepreneurs - i.e. individuals that own and manage a business (1,213 observations). The survey has detailed information on entrepreneurial income which, lacking a proxy of TFP, we use as a measure of entrepreneurial ability.<sup>26</sup> The SHIW reports also the date and province of birth and the province of residence where the individual has his/her business, as well as the income from various sources and a rich set of demographic characteristics. We then match each entrepreneur with the number of firms in the province of birth at learning age, using census data on the number of firms in the province, as well as with number of firms in the province where he/she is currently located. The first should capture the effect of learning opportunities and the second current local externalities. Given that we only know the current location and that at birth, we assume that the location in the early phase of the working career is the same as the one at birth.<sup>27</sup>

Identification of the two effects comes from two sources: from the changes in the number of firms over time and, most importantly, from movers - individuals that were born in a province and are now entrepreneurs in another: these account for about 20% of our sample. Indeed, this second sample is crucial to disentangle the effects of the number of firms at learning age from the current number: the correlation between the two variables is 0.66 in the whole sample; but it is 0.91 among non-movers and -0.0316 among movers. We then run a regression of the entrepreneurial income (in logs) on the number of firms in the province where the individual was at learning age and the number of firms where he/she currently lives and a full set of year dummies, birth-cohort dummies, industry dummies, gender and education dummies, four area of birth and four area of residence dummies to account for other potential local effects on entrepreneurial income.

The results are reported in Table 11, where, to save on space, we report in each row the results of one regression. In the first two rows we assume that learning takes place at age 25 and match the number of firms accordingly. The first row inserts as a regressor only the number of firms at learning age; its coefficient is positive and highly statistically significant

---

<sup>26</sup>Recall that in the Lucas model TFP and profits move one to one.

<sup>27</sup>This is likely to introduce some measurement error if the entrepreneur was located elsewhere at learning age. If anything, this should bias the estimated coefficient downwards.

and its size implies an elasticity of about 10%, a non trivial effect. In the second row we add the number of firms in the province where the entrepreneur is currently located; the coefficient on this variable is small and statistically insignificant while the coefficient on the number of firms at learning age is unchanged, in sign and significance. Taken literally, this result implies that learning entrepreneurial abilities, rather than other types of local externalities, drives the correlation between productivity and the number of firms.

The third and fourth rows show results assuming that the acquisition of entrepreneurial abilities occurs even earlier, at age 15. The coefficients are estimated somewhat less precisely but they are very similar to those in the first two columns. In the next two rows we restrict the sample to 245 movers since most of the identification comes from them. When we do this the estimated elasticity of entrepreneurial income to the number of firms in the province of origin at age 25 is 0.148, a third larger than in the whole sample, while the number of firms in the province where he/she is currently located has no explanatory power. To make sure this result is not driven by the number of firms reflecting selection, in the last two columns we report the second stage of a two-step Heckman estimate adjusted for selection. The first stage of the moving decision includes all second stage regressors and dummies for the size of the city of residence and marital status, which we use as exclusion restrictions to achieve identification. The estimated effect of the number of firms at learning age is essentially the same as in the previous two columns and, as before, the number of firms in the current location is not statistically significant.

The results for movers are difficult to reconcile with stories other than learning abilities; furthermore, they allow one important interpretation issue of the findings in the previous sections to be addressed. Even if the positive correlation between a firm TFP and the number of firms in the local labor system reflects learning, one may argue that it is the learning of the workers rather than that of the entrepreneur which is driving the result. At the very least, the estimates in Table 11 imply that entrepreneurial learning is contributing to that correlation.

## 7 Conclusions

This paper has compared two alternative theoretical models of cluster formation, one based on the cost of setting up a business and another on the costs of learning entrepreneurial ability. We have shown that these models carry quite different implications on the sign of the correlation between entrepreneurial ability and entrepreneurial incidence, defined as number of firms over total population. This relation is negative if geographical agglomeration of firms is due to start-up costs and positive if it is due to differences in learning opportunities. The models have also clear-cut implications for the relation between entrepreneurial incidence and the frequency mass at the two tails of the ability distribution. We have confronted these theoretical predictions with data on a large sample of Italian manufacturing firms coupled with information on the geographical clusters the firms belong to. We have found overwhelmingly that the start-up cost model is rejected and the learning hypothesis supported. The conclusions are robust to sample selection, estimation methods and, more importantly, controls for technological spillovers and learning human capital skills. We have also found additional support for specific predictions of the learning model versus other types of learning externalities. We have also found additional supporting evidence for specific predictions of the learning model.

Putting these results in perspective, the paper introduces the idea that entrepreneurial talent can be learned and provide supporting evidence. To the best of our knowledge this is the first paper to pursue some of the implications of the idea that the talent to become an entrepreneur is learnable. The fact that entrepreneurship can be acquired through costly learning has far-reaching implications, especially for policies designed to stimulate the emergence of entrepreneurs. At the very least, it implies that the abatement of start-up costs may have not only the direct effect of allowing individuals with inherited ability to become entrepreneurs, but also the perhaps more important effect of boosting entrepreneurship through accumulation of entrepreneurial abilities triggered by the larger number of firms.

Finally, the paper contributes to the debate on the determinants of TFP at the level of firm and locality. We provide evidence that differences in TFP may be traced back to the abilities of entrepreneurs and that ability can be accumulated. If abilities were innate, then differences in the firm-level component of the Solow residual would simply

reflect the distribution of the original endowment of talent leaving little hope for measures to increase firms' TFP. Further, if start-up costs were the same across areas, the moments of the distribution of firm-level TFP should also be the same, since it is unlikely that individuals in certain areas are born with better talent for entrepreneurship than those in others. If, however, entrepreneurial ability can be learned, then systematic factors affecting the learning process can be identified and these in principle could be modified by policy actions. Our findings suggest that the number of firms in an area is itself a powerful factor for learning how to be an entrepreneur.

## A Appendix: endogenizing the learning decision

In this appendix we briefly show how to endogenize the learning decision. Assume that, before deciding whether to become an entrepreneur, an individual decides to invest in learning such capabilities. Learning takes place partly while on the job (e.g. by observing the internal organization of the firm and learning about its suppliers) and partly out of the job (e.g. by interacting and talking with other workers and entrepreneurs). Let  $I$  the amount invested in acquiring abilities; learning costs  $\alpha I$  where  $\alpha$  is marginal cost of investing in learning.

Assume that investment in learning influences the distribution of EA which is parametrized by the investment  $I$  undertaken in the learning phase:

$$\tilde{x} \sim \gamma(\cdot, I); \Gamma(x, I)$$

is the cumulative distribution function. We assume that  $\partial\Gamma/\partial I < 0$ : higher investment shifts the probability distribution to the right in the first order stochastic dominance sense. Once the EA is realized, the problem faced by the agent is identical to the one in the previous section.

The expected return from investing  $I$  given the entry cost  $c$  is

$$D(I) = w\Gamma(z, I) + \int_z^{\bar{x}} \pi(x)\gamma(x, I)dx - (1 - \Gamma(z, I))c$$

where  $\Gamma(z, I)$  is the probability that ability turns out to be below the cutoff value  $z$  and  $\int_z^{\infty} \pi(x)\gamma(x, I)dx$  is the expected profits conditional on becoming an entrepreneur. The agent solves the problem:

$$\max_I \{D(I) - \alpha I\}$$

Let  $I^*(\alpha)$  denote the optimal investment in learning abilities; it is easy to show that  $\frac{dI^*}{d\alpha} < 0$ . Then, under the same assumptions in the text

$$\frac{d(1 - \Gamma(z, I^*))}{d\alpha} = -\frac{\partial\Gamma(z, I^*)}{\partial I^*} \frac{dI^*}{d\alpha} < 0,$$

so that localities with lower learning costs will have a higher entrepreneurial density. The effect on entrepreneurial quality is obtained as in the text.

10	TEq	0.74	0.26	0.70*** (.008)	0.26* (.144)	0.96 (.144)

Note:  $\alpha$  is the capital coefficient and  $\beta$  the labor coefficient. The first estimates use the traditional Solow approach, the second the direct estimation of the production function coefficients using the Olley and Pakes (1996) procedure. Standard errors in parenthesis. Standard errors for the capital coefficient and for the sum of the coefficients computed by a bootstrapping procedure based on 150 replications. In column 4 and 5, \*\*\* indicates significance at 1%, \*\* at 5% and \* at 10% (assuming normality for the bootstrapped standard errors). In column 6, the null  $H_0 : \alpha + \beta = 1$  is never rejected at standard significance levels. See Table 1 for the industry labels.

Table 3: Ability and other characteristics by density of LLS

Variable	Total sample		High-density LLS		Low density LLS	
	Mean	S.D.	Mean	S.D.	Mean	S.D.

No. firms in LLS-ind.	5.49	1.82	5.81	1.72	4.28	1.67
No. workers in LLS	10.02	1.68	10.33	1.54	6.47	2.35
No. workers in LLS-ind.	8.07	2.27	8.49	2.05	6.47	2.35
Int. inputs/VA in LLS	.88	.25	.87	.21	.89	.37
Int. inputs in LLS-ind.	.83	.43	.83	.37	.83	.60

All non dichotomous variables in log. High-density LLS are defined as those with the total number of firms over the population in the LLS above the median value by LLS. Ability is the estimate of TFP.  $I_{[Ability < 25\%]}$  is 1 if the ability is below the 25<sup>th</sup> percentile of the ability distribution and zero otherwise. Ability and capital stock is from the CB sample; the number of firms and of workers are computed from the INPS dataset (the population).

Dependent variable: ability in Panel A (OLS estimates);  $I_{[Ability < 25\%]}$  in Panel B;  $I_{[Ability > 75\%]}$  in Panel C (Probit estimates). The number of firms, capital and labor are in logs and computed at the LLS-industry level. Standard errors adjusted for clustering at the LLS-sector-year level. See Table 4 for the explanation of the specifications.

Dependent variable: ability in Panel A;  $I_{[Ability < 25\%]}$  in Panel B;  $I_{[Ability > 75\%]}$  in Panel C (linear probability estimates). The first three columns report OLS estimates; the fourth to sixth columns are IV estimates. The instrument is the population in the LLS in 1861. The Number of firms is in log and computed at the LLS-industry level. Standard errors adjusted for clustering at the LLS-sector-year level. See Table 4 for the explanation of the specifications.

Dependent variable: ability in Panel A (OLS estimates);  $I_{[Ability < 25\%]}$  in Panel B;  $I_{[Ability > 75\%]}$  in Panel C (Probit estimates). The Number of firms is in log and computed at the LLS-industry level. “Small” is a dummy =1 if the capital stock is below the median, calculated within each LLS-industry-year cell. Standard errors adjusted for clustering at the LLS-sector-year level. See Table 4 for the explanation of the specifications.

Geo controls	MA	MA	MA	Prov	Prov	Prov

Dependent variable: ability in Panel A (OLS estimates);  $I_{[Ability<25\%]}$  in Panel B;  $I_{[Ability>75\%]}$  in Panel C (Probit estimates). The number of firms is in log and computed at the LLS-industry level; “Dispersion” is the log of the standard deviation of the capital stock within each LLS-industry-year cell. Standard errors adjusted for clustering at the LLS-sector-year level. See Table 4 for the explanation of the specifications.

Table 11: The effect of the number of firms at “learning age”

Regressions	Variables			R <sup>2</sup>	No. obs
	log No. of firms at learning age	log current No. of firms	Mill’s ratio		
Learning age = 25	0.096*** (.036)			.184	1,213
	0.119*** (.023)	−.028 (.059)		.184	1,213
Learning age = 15	0.079*** (.027)			.154	1,106
	0.092* (.053)	−.008 (.053)		.154	1,106
Only movers	0.148*** (.0738)			.315	245
	0.147*** (.0738)	−.028 (.042)		.315	245
Selection adjusted	0.154*** (.0703)		−0.121 (.284)		1,212
	0.149*** (.0693)	−.027 (.063)	−0.193 (.281)		1,213

Each row reports the results of one regression. Dependent variable: log of entrepreneurial earnings. The number of firms at learning age is the log of the total number of firms in the province of birth of the entrepreneur at learning age, i.e. when he was 25 (first two rows and rows 5-8 ) or 15 (rows 3 and 4); the current number of firms is the log of the current number of firms in the province of residence of the entrepreneur in the current survey year. All regressions include year and birth cohort dummies, area of residence and area of birth dummies, industry dummies and gender and education dummies. Standard errors adjusted for clustering at the province level.
